March 2023

ABSTRACT

This paper develops a model of heterogeneous agents and international trade. Heterogeneous agents are modeled as in the standard incomplete markets tradition with households facing incomplete insurance against idiosyncratic productivity and taste shocks. Trade in goods follows the Armington tradition but is derived from the “bottom up” with micro-level heterogeneity shaping aggregate trade. I show how micro-level trade elasticities, trade, and the gains from trade vary with a household’s wealth and how self-insurance motives shape these outcomes. In aggregate, the pattern of trade is distorted relative to the efficient allocation and the gains from trade deviate from standard benchmarks. Quantitatively, I compute the multi-country, asymmetric global economy and calibrate it to match bilateral trade flows for 19 countries. I use the model to measure the gains from trade and the ability of trade policy to improve outcomes.

Email: michael.e.waugh@gmail.com. The views expressed herein are those of the author and not necessarily those of the Federal Reserve Bank of Minneapolis or the Federal Reserve System. This project was developed with research support from the National Science Foundation (NSF Award number 1948800).

This paper develops a model of heterogeneous households and international trade. From the perspective of trade, household heterogeneity is interesting because of the notion that some benefit from trade and others don't. An aspect of these unequal gains relates to the idea is that rich and poor consumers have different price elasticities and, thus, they shape the expenditure patterns at the micro and macro level. I run with this idea and develop a model with heterogeneous price elasticities featuring prominently and then explore the positive and normative implications of the model for trade.

The building blocks to my model are well known: household heterogeneity is induced via the standard incomplete markets model (Bewley, Huggett (1993), Aiyagari (1994)) with households facing incomplete insurance against idiosyncratic productivity and taste shocks. Trade in goods follows the Armington tradition with producers in each country producing a national variety. The twist is that households have random utility over these varieties and they make a discrete choice over the varieties to consume in addition to their savings decisions. The explicit aggregation of household-level decisions then determines aggregate trade flows, trade elasticities, and the gains from trade

The first part of the paper works out how household behavior translates into aggregates. Aggregate trade takes on a mixed-logit form similar to Berry, Levinsohn, and Pakes (1995) with two interesting differences. First, a household's choice of the variety and quantity is a dynamic decision and is intertwined with a household's inter-temporal savings choice. Second, the mixing distribution—over which demands are aggregated—is endogenous and depends upon household behavior as it determines the distribution of wealth in equilibrium. Outside of a knife-edge case that I discuss below, this is a model where households' savings motives at the micro-level determine trade at the aggregate level.

The key force through which heterogeneity matters are trade (price) elasticities that vary with income and wealth at the household-level. Behind the math is the intuitive idea that poor households strongly value extra consumption—independent of the variety—as their marginal utility of consumption is high. So, poor households are very sensitive to price and then concentrate their expenditure on the cheapest commodity available. In contrast, rich households' marginal utility of consumption is low, likely consume their ideal variety, and are less sensitive to changes in prices. In aggregate, the pattern of trade and the response of trade to shocks—the aggregate trade elasticity—depends upon the micro-level trade elasticities and the distribution of demand.

I further characterize the gains from trade in this economy and show how they reflect several new forces. First, I show how one aspect of the household level gains from trade reflect the expected, discounted stream of changes in an individual's "home choice probability," similar in spirit to the result of Arkolakis, Costinot, and Rodríguez-Clare (2012), but different in that

these gains are heterogenous across households.

A second force at the household-level is how a liberalization changes a household's valuation of its net asset position. The issue is that a trade liberalization will change interest rates and lead to winners and losers depending upon a households' net asset position. For example, if a trade liberalization leads to an increase in interest rates, net debtors suffer since their terms to borrow deteriorated, while net savers benefit. Why might a trade liberalization change interest rates? It's because the liberalization has heterogenous effects on expenditure patterns and savings. And because the distribution of savings changes, to clear the asset market interest rates must adjust. The novelty here is how the goods trade and the financial market are interlinked—not separate as they are typically treated.

Before moving on to the quantitative work, I explore two special cases. The first case is the efficient allocation where a planner can reallocate resources and overcome market incompleteness. In this case, I recover “first-best intuition” in that the gains from trade only reflect the direct savings associated with a reduction in trade costs. In this allocation, changes in expenditure patterns are not relevant via an envelope theorem argument—the planner already sources goods from the correct places so there are no gains from expenditure switching. While my economy is all about heterogeneity on the household side, this result is very reminiscent of Atkeson and Burstein's (2010) result on the irrelevance of firm heterogeneity in an economy where the allocation is efficient. Thus, the core issues at play in my model are not household heterogeneity per se, but inefficiencies induced by market incompleteness.

The second special case that I consider is when the utility function over the physical commodity is log. With log utility, I obtain a separation result where aggregate trade outcomes “separate” from household heterogeneity. Trade takes a constant elasticity form with the trade elasticity pinned down by the dispersion parameter on the taste shocks similar to Eaton and Kortum (2002). And the trade elasticity and the share of home purchases summarize the gains from trade like in Arkolakis et al. (2012). This case is also interesting because Anderson, De Palma, and Thisse (1987) showed that in a model with log utility and additive logit shocks, the economy behaves *as if* there were a representative agent CES consumer. In my economy, my suspicion was that market incompleteness and household intertemporal behavior would nullify the Anderson et al.'s (1987) result—it does not.

Quantitatively, I make a contribution by computing and estimating the model at a scale typically reserved for static trade models. As a testing ground, I focus the data set of Eaton and Kortum (2002). The 19 countries in this data set is about the right size (still easy to do on modern desktop) to illustrate how a very rich model like this can work in a multi-country setting. Moreover, the Eaton and Kortum (2002) data set provides a well defined benchmark disciplined by bilateral trade flows and gravity variables, so it's a nice laboratory to explore new issues within.

The calibration challenge is the following.¹ The model does not admit a “gravity” representation of trade flows that allows researchers to invert trade frictions and productivity levels from trade flows as done, e.g., in Eaton and Kortum (2002). Similarly, the model does not admit the use of “exact-hat algebra” which allows the research to construct counterfactuals without knowledge to primitives like trade frictions or productivity (see, e.g., the approach articulated in Costinot and Rodríguez-Clare (2014)).

My solution is to use the insight that the regressions employed in gravity frameworks provide very accurate descriptions of the data generating process (which is sometimes thought as validation of the model behind the gravity regression). Rather than treating the gravity regression as a structural relationship, I use it as a guide and use an indirect inference procedure where I estimate parameters of the model so that the regression coefficients from a standard gravity regression run on my model’s data match that seen in the data set of Eaton and Kortum (2002).

1. The Heterogeneous Agent Trade Model

This section describes the model and then defines the decentralized competitive equilibrium. Trade is in the Armington tradition with each country producing a nationally differentiated variety. Households face the “income fluctuations problem” as in the standard incomplete markets tradition (see, e.g., Chapter 17 of Ljungqvist and Sargent (2012)).

The key twist is that I do not employ modeling techniques with aggregation at household level across national varieties. Instead, I lean into the household heterogeneity and have households make a discrete choice over the varieties they consume in addition to their savings decisions. Aggregate trade flows, trade elasticities, and the gains from trade are then defined by the explicit aggregation of household-level decisions to purchase different varieties, their elasticity of demand, and their gains from trade.

1.1. Production and Trade

There are M locations which I call a country. Each country produces a nationally differentiated product. In country i , competitive firms’ production technology to produce variety i is:

$$Q_i = A_i N_i, \tag{1}$$

¹Separate from this is computational challenge. Finding an equilibrium requires (i) solving for households dynamic problems—in each country (ii) constructing the stationary distribution of expenditure patterns and wealth—in each country (iii) aggregating and then (iv) finding a vector of prices so goods markets and financial markets clear world wide. Plot twist: It’s doable. My github repository and the Appendix provides a complete description of my approach and methods.

where A_i is total factor productivity and N_i are the efficiency units of labor supplied by households in country i .²

In the next several sections, I focus on only one type of barrier to trade: there are iceberg trade costs $d_{ij} > 1$ for a good to go from supplier j to buyer i .

Profit maximization of the producers in location i results in the wage per efficiency unit reflecting the value of the marginal product of labor

$$w_i = p_i A_i. \quad (2)$$

Given iceberg trade costs, the unit cost for country i to purchase a good from location j is

$$p_{ij} = \frac{d_{ij} w_j}{A_j}. \quad (3)$$

This is the trade and production side of the model. While sparse, it's worth reminding you that with a representative agent and a constant elasticity Armington aggregator much comes out of this model. There is a "gravity equation" relating bilateral trade flows to country characteristics with a constant trade elasticity. And there are two sufficient statistics (the trade elasticity and home trade share) that globally characterize the welfare gains from trade. In the next section, I give up on the representative agent.

1.2. Households

There is a mass of L_i households in each country. Households are immobile across countries. They are infinite lived and have time-separable preferences over consumption of varieties:

$$E_0 \sum_{t=0}^{\infty} \beta^t \tilde{u}(\{c_{ijt}\}_M), \quad (4)$$

where the notation $\{c_{ijt}\}_M$ means that the household has preferences over all j varieties supplied by M countries in the world. Here I'm indexing things by ij to denote the variety j that is consumed in location i .

Households' period utility function is of the random utility class and each period households can only consume one variety. The utility associated with the choice of variety j is

$$\tilde{u}(c_{ijt}) = u(c_{i,t}) + \epsilon_{jt}. \quad (5)$$

where the ϵ_{jt} are iid random variables across time, households, and countries. For the analysis,

²Note that lack of physical capital in the model. Households here are saving in via pure exchange of non-state contingent IOUs as in Huggett (1993) rather than in physical capital as in Aiyagari (1994).

I assume that these shocks are distributed Type 1 Extreme Value with CDF

$$F(\epsilon) = \exp(-\exp(-\sigma_\epsilon^{-1}\epsilon)) \quad (6)$$

where σ_ϵ is the dispersion parameter. A useful generalization of this setting to a multi-sector model is the “infinite shopping isle” approach of Mongey and Waugh (2022) where these shocks take on a Generalized Extreme Value representation and then households choose the sector and then the variety each period.

For now, all I assume that the utility function over the physical good c_{ijt} is well behaved. In the analysis below I explore different specifications of the utility function u over the physical commodity and I highlight the rather unique case of log utility.

A household’s efficiency units are stochastic and they evolve according to a Markov chain. So, z is a household’s efficiency units and $\mathcal{P}(z, z')$ describes the probability of a household with state z efficiency units transiting to state z' . Again, I assume that \mathcal{P} is well behaved in the necessary ways.

Households can save and borrow in a non-state contingent asset a . One unit of the asset pays out with gross interest rate R_i next period. I discuss this more in depth below, but the determination of R_i is with that which clears the bond market (local or global). A country specific, exogenous debt limit ϕ_i constrains borrowing so:

$$a_{t+1} \geq -\phi_i. \quad (7)$$

All these pieces come together in the household’s budget constraint, conditional on choosing variety j to consume, and focusing on a stationary setting where prices are constant:

$$p_{ij}c_{ijt} + a_{t+1} \leq R_i a_t + w_i z_t. \quad (8)$$

The value of asset purchases and consumption expenditures must be less than or equal to asset payments and labor earnings.

1.3. The Household Problem

The state variables of a individual household are its asset holdings and efficiency units. As alluded to above, for now I focus on a stationary setting where aggregates are not changing and, thus, I abstract from carrying the notation associated with them around.³

³If you *do* want to carry them around, notice that all that households in each country care about are prices (today and in the future). The distributions of households in other countries, per se, don’t matter. Thus, the relevant aggregate states in country i are $[\{w_i\}_M, R_i]$ which is the collection wage per efficiency units and the interest rate.

The value function of a household in country i , after the variety shocks are realized, is

$$v_i(a, z) = \max_j \{ v_i(a, z, j) \} \quad (9)$$

which is the maximum across the value functions associated with the discrete choices of different national varieties. The value function conditional on a choice of variety is

$$v_i(a, z, j) = \max_{a'} \left\{ u(c_{ij}) + \epsilon_j + \beta \mathbb{E}[v_i(a', z')] \right\} \quad (10)$$

subject to (7) and (8)

where households choose asset holdings and the level of consumption is residually determined through the budget constraint. Associated with the solution to this problem is a policy function $g_i(a, z, j)$ which solves (10) and maps current states into asset holdings tomorrow a' contingent upon the variety choice j . The continuation value function on the right-hand side of (10) is the expectation over (9) with respect to (i) efficiency units next period, z' and (ii) the variety taste shocks. An implication of this is that households understand that there may be situations where they really desire, say, a high priced imported good and, hence, save accordingly.

The Type 1 extreme value distribution on the taste shocks give rise to the following choice probabilities for each differentiated good:

$$\pi_{ij}(a, z) = \exp \left(\frac{v_i(a, z, j)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{v_i(a, z, j')}{\sigma_\epsilon} \right), \quad (11)$$

which is the probability that a household with assets a and efficiency units z chooses country variety j . And then the expectation of (9) with respect to the taste shocks takes the familiar log-sum form

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{v_i(a, z, j')}{\sigma_\epsilon} \right) \right\}. \quad (12)$$

Associated with this problem in (10) for non-borrowing-constrained households is a Euler Equation for each variety choice j :

$$\frac{u'(c_i(a, z, j))}{p_{ij}} = \beta R_i \mathbb{E}_{z'} \left[\sum_{j'} \pi_{ij'}(a', z') \frac{u'(c_i(a', z', j'))}{p_{ij'}} \right]. \quad (13)$$

This has a very natural interpretation: a household equates marginal utility of consumption

today with expected discounted marginal utility of consumption tomorrow adjusted by the return on delaying consumption. The interesting feature here is that the expected value of the marginal utility of consumption reflects the uncertainty over one's preference over different varieties tomorrow via the choice probabilities. And note that households has some control over these probabilities as the asset choice today influence the choice probabilities tomorrow.

Before moving on to aggregation, I make one useful observation that assists the analysis. Stare at (11) and (12) long enough, one can arrive at a dynamic, sufficient statistic representation of $v_i(a, z)$. Appendix C works through the individual steps, but (12) can be summarized as

$$v_i(a, z) = -\sigma_\epsilon \log \pi_{ii}(a, z) + u(c_i(a, z, i)) + \beta \mathbb{E}_{z'} v_i(a', z'). \quad (14)$$

Here the ex-ante value function (prior to the realization of the preference shocks) is expressed as a sum of the log home choice probability, utility over physical consumption of the home good, and recursively the expected value function tomorrow. What's going on here is that the home choice probability π_{ii} summarizes the expected value of the taste shocks, their benefits, and how households respond to them in the future.⁴

Equation (14) together with (13) also provides more insight about how households' savings motives interact with the variety choice. Focusing on a household consuming the home good (and note that the left-hand-side below could be for any variety choice), the Euler Equation in (13) becomes:

$$\frac{u'(c_i(a, z, i))}{p_{ii}} = \beta \mathbb{E}_{z'} \left\{ -\sigma_\epsilon \frac{\partial \pi_{ii}(a', z') / \pi_{ii}(a', z')}{\partial a'} + \frac{u'(c_i(a', z', i)) R_i}{p_{ii}} \right\}, \quad (15)$$

which says that an unconstrained household should be indifferent between the marginal utility of consumption forgone to hold some more assets and two components: (i) the benefit from how a change in assets changes in their variety choice in the future and this is summarized by the change in the home choice probability and (ii) the direct benefit of the returns on the assets evaluated at the marginal utility of consumption.

⁴Home choice probabilities are not necessarily the same as home trade shares, but this is closely related to Equation (15), Footnote 42 of Eaton and Kortum (2002) and I'm heading towards situations where this result plus restrictions on u give rise to the result in Arkolakis et al. (2012).

1.4. Aggregation

Aggregation. At the core of aggregation is a probability distribution $\lambda_i(a, z)$ describing the measure of households across the individual states. This distribution evolves according to

$$\lambda_i(a', z') = \sum_j \int_z \int_{a: a'=g_i(a, z, j)} \pi_{ij}(a, z) \mathcal{P}(z, z') \lambda_i(a, z) da dz. \quad (16)$$

where the inner most term describes the mass of households choosing variety j , multiplied by the probability that z transits to z' , multiplied by the existing measure of households with states a and z . This is integrated with respect to those actually choosing asset holdings a' , over all z 's, and then summed over the different variety choices.

Given this distribution, everything else follows. First focusing on trade, aggregate bilateral imports are

$$M_{ij} = L_i \int_z \int_a p_{ij} c_i(a, z, j) \pi_{ij}(a, z) \lambda_i(a, z) da dz. \quad (17)$$

Here imports take on a mixed logit formulation that very much mimics that used in the industrial organization literature, e.g, Berry, Levinsohn, and Pakes (1995).

There are, however, several interesting differences in that there is an active intensive margin (not unit demand) and inside the choice probability $\pi_{ij}(a, z)$ is the non-linear value function from (9). These features are interesting because they're determined by the dynamic features of the household problem. The household's inter-temporal choice to save determines the quantity choice. And because the choice probability reflects the value function, it embeds forward looking behavior of the household.

The third interesting feature is that the mixing distribution—over which demands are aggregated—is endogenous. Through the law of motion in (16) household behavior determines the distribution of wealth. So it's not a free parameter and it will change with changes in primitives of the environment.

Similar to imports, aggregate bilateral exports from country i to country j are

$$X_{ji} = L_j \int_z \int_a p_{ji} c_j(a, z, i) \pi_{ji}(a, z) \lambda_i(a, z) da dz. \quad (18)$$

The value of aggregate consumption is

$$\widetilde{P_i C_i} = L_i \sum_j \int_z \int_a p_{ij} c_i(a, z, j) \pi_{ij}(a, z) \lambda_i(a, z) da dz \quad (19)$$

In (19), one can see both a bug and a feature of this model. Here there is an “index number problem” in the sense that there is not an ideal price index for which one can decompose aggregate values into a price and quantity component. This is in contrast to, e.g., a model where households consume a CES bundle of goods.

Finally, the aggregate quantity of asset holdings integrates across the asset choices of individual households

$$A'_i = L_i \sum_j \int_z \int_a g_i(a, z, j) \pi_{ij}(a, z) \lambda_i(a, z) da dz. \quad (20)$$

which integrates over the asset choices—given the policy function $g_{ij}(a, z)$ and variety choices $\pi_{ij}(a, z)$. And then sum's across the different varieties available.

National Accounting. From here, I reconstruct national income and product identities. Starting from the production side, aggregate efficiency units are

$$N_i = L_i \int_z \int_a z \lambda_i(a, z) da dz. \quad (21)$$

and from here we can connect the value of aggregate production must equal aggregate payments to labor so

$$p_i Y_i = p_i A_i N_i = L_i \int_z \int_a w_i z \lambda_i(a, z) da dz, \quad (22)$$

Then by summing over individual consumers' budget constraint and substituting in (22), the aggregated budget constraint is:

$$p_i Y_i = \widetilde{P_i C_i} + \left[-R_i A_i + A'_i \right], \quad (23)$$

where national income equals the value of aggregate consumption $\widetilde{P_i C_i}$ and the country's net factor payments and net asset position. To arrive at the standard national income accounting identity, simply work with the relationship between production, exports, and aggregate consumption in (19) and imports gives rise to

$$p_i Y_i = \widetilde{P_i C_i} + \left[\sum_{j \neq i} X_{ji} - \sum_{j \neq i} M_{ij} \right], \quad (24)$$

where national production or GDP equals consumption plus exports minus imports. A comparison of (23) and (24) then makes clear that the trade imbalance is connected with a country's net factor payments and net asset position.

Beyond accounting, this last observation shows how trade flows are interlinked with financial flows. Inspection of the individual elements in (17), (20), and the households' budget constraint reveal that household's asset positions are intertwined with trade flows through both the intensive (how much to consume and, hence, save) and the extensive margins (which variety to consume). Thus, a feature of this model is that the trade side is interlinked with the financial side of the economy in a non-trivial way.

1.5. The Decentralized Equilibrium

In this section, I discuss the market clearing conditions that an equilibrium must respect and then define the Decentralized Equilibrium of this economy.

The Goods Market. Goods market clearing equates the value of production of commodity i with global demand for country i 's commodity:

$$p_i Y_i = \sum_j X_{ji}, \quad (25)$$

where the left hand side is production and the right hand side is world demand for the commodity (via exports) from (18).

The Bond Market. The second market clearing condition is the bond market. There are two case worth thinking about here. One is of "financial autarky" in which there is a local bond market that facilitates within country asset trade, but not across countries. In this case, there is an interest rate R_i for each country and the associated market clearing condition is

$$A'_i = 0, \quad \forall i \quad (26)$$

which says that net asset demand within each country i must be zero. As is common in the trade literature, this condition implies that trade is balanced—just stare at (23) and (24). Yet, even with balanced trade, there is still within country trade of financial assets. Some households are savers, others are borrowers and the interest rate is that which the net asset position is zero.

The second case is of "financial globalization" where there is a global bond market that facilitates both within country asset trade, and across countries. In this case, there is a single interest rate R and the associated market clearing condition is

$$\sum_i A'_i = 0 \quad (27)$$

In this case trade need not be balanced for each country. Here a specific country might run, say, a trade deficit because at the given prices, the total amount of borrowing within a country is larger than the total amount of saving. However, across all countries total borrowing must

equal total saving.

Below I formally define the Decentralized Stationary Equilibrium where private market participants taking prices as given solve their problems, the distribution of households is stationary, and prices are consistent with market clearing.

The Decentralized Stationary Equilibrium. A Decentralized Stationary Equilibrium are asset policy functions and commodity choice probabilities $\{ g_i(a, z, j), \pi_{ij}(a, z) \}_i$, probability distributions $\{ \lambda_i(a, z) \}_i$ and positive real numbers $\{ w_i, p_{ij}, R_i \}_{i,j}$ such that

- i Prices (w_i, p_{ij}) satisfy (2) and (3);
- ii The policy functions and choice probabilities solve the household's optimization problem in (9) and (10);
- iv The probability distribution $\lambda_i(a, z)$ induced by the policy functions, choice probabilities, and primitives satisfies (16) and is stationary;
- v Goods market clears:

$$p_i Y_i - \sum_j^M X_{ji} = 0, \quad \forall i \quad (28)$$

- v Bond market clears with either

$$A'_i = 0, \quad \forall i \quad \text{or} \quad \sum_i A'_i = 0 \quad (29)$$

1.6. Outline of the rest of paper

This model above has households making individual choices over national varieties, savings, all while facing productivity and taste shocks. Explicit aggregation of household behavior determines the pattern of trade and this is linked with trade in financial assets. The remaining sections of the paper work through the following questions:

1. **What does the efficient, centralized allocation look like?** The model features an inefficiency arising from market incompleteness. Households would like insurance against future shocks to income and taste shocks, but only have a partial ability to provide themselves this insurance. Endowing a central planner with the ability to overcome this friction and studying the resulting allocation helps illustrate the behavior of model in the decentralized allocation.
2. **What are the gains from trade in decentralized allocation?** Here, surprisingly, a lot can be said. I connect the results with those from the Centralized Allocation. I also work-

out a knife edge case when utility is log over consumption and how it delivers complete separation between the heterogenous agent side of the economy and trade.

3. **What are the quantitative implications of this model?** In this section, I calibrate the model essentially replicating the analysis of Eaton and Kortum (2002) by selecting trade costs and productivity parameters so that bilateral trade flows in the model line up in the data. I then perform several counterfactuals to illustrate the mechanics of the model and make comparisons to the model of Eaton and Kortum (2002) and the response of the centralized allocation.

2. The Centralized Allocation

This section describes the Centralized (Efficient) Allocation. The starting point is a stance on the social welfare function. I focus on a additive social welfare:

$$W = \sum_{t=0}^{\infty} \sum_i \int_z \beta^t \psi_i v_i(z, t) L_i \lambda_i(z, t),$$

and here $v_i(z, t)$ is a households ex-ante utility (before preference shocks are realized) with state z , time t , in country i . The ψ_i terms are country specific Pareto weights. And $\lambda_i(z, t)$ is the distribution of households in country i across productivity states at date t . Now unpack the benefits from physical commodity and the preference shock in the following way:

$$W = \sum_{t=0}^{\infty} \sum_i \sum_j \int_z \beta^t \psi_i \left\{ u(c_i(z, j, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (30)$$

so the inner term is period utility given the associated consumption allocation and then the expected value of the preference shock conditional on the choice probability $\pi_{ij}(z, t)$. This inner term is then weighted by the number of households that receive that utility, i.e., the choice probability times the mass of households with shock z at date t . The sum across j adds up all households in country i . Then the sum across i reflects that this is global welfare.

The Planner chooses consumption allocations $c_i(z, j, t)$ and choice probabilities $\pi_{ij}(z, t)$ for all i, j pairs, z states, and dates t to maximize (30). This maximization problem is subject to two constraints. The first is the resource constraint:

$$Y_{it} \geq \sum_j \int_z d_{ji} c_j(z, i, t) \pi_{ji}(z, t) L_j \lambda_j(z, t), \quad (31)$$

which says that production of variety i must be greater than or equal to world consumption of variety i inclusive of trade costs d_{ji} . The second constraint is that the choice probabilities are

probabilities and sum to one:

$$1 = \sum_j \pi_{ij}(z, t). \quad (32)$$

Given these constraints I define the **Centralized Planner's Problem** as the following:

$$\max_{c_{i,j}(z,t), \pi_{i,j}(z,t)} \sum_{t=0}^{\infty} \sum_i \sum_j \beta^t \int_z \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (33)$$

$$\text{subject to (31), (32) and an initial condition } \lambda_i(z, 0). \quad (34)$$

In Appendix A, I derive the solution to this problem. Proposition 1 describes the allocation that maximizes social welfare and I will call this allocation the Efficient Allocation.

Proposition 1 (The Centralized (Efficient) Allocation) *The allocation that satisfies the Centralized Planning Problem in (33) is:*

1. A consumption allocation satisfying:

$$\psi_i u'(c_{ij}(z, t)) = \chi_j(t) d_{ij} \quad (35)$$

where $\chi_j(t)$ is the shadow price of variety j .

2. The choice probabilities are

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t))c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t))c_{ij'}(t)}{\sigma_\epsilon} \right) \quad (36)$$

and are independent of z because of (35).

Proposition 1 has some neat features. First, the consumption allocation takes on the natural feature that the (Pareto-weighted) marginal utility of consumption equals its shadow price adjusted by the trade friction. Here the shadow price is the multiplier $\chi_j(t)$ on the resource constraint in (31). Because the shadow price only reflects the scarcity of the commodity, the marginal utility of consumption (and consumption) then does not depend upon the household's state z . So if a household is productive or unproductive at date, t , the Planner equates the marginal utility of consumption across these states—within variety. This is the sense in which the planner is providing full insurance across households.

Another implication of (35) is that the marginal utility of consumption is *not* equated across all households within a country as one would typically expect in a one good model. (35)

implies that the ratio of the marginal utility of consumption—adjusted by relative shadow prices—should be equal. This is like a within-country Backus and Smith (1993) condition.

The second part of Proposition 1 prescribes the mass of households that consume variety j . Per the distributional assumption on the taste shocks, the choice probabilities in (36) take the form of ratio's of exp relative to sum of exp functions with the dispersion parameter σ_ϵ showing up in the natural way.

The interpretation of the terms within the exp function take on a very intuitive form: it's the net social benefit of assigning a household to consume that variety.⁵ Net is here because it's the difference between the utility received $u(c_{ij}(t))$ minus the social cost $u'(c_{ij}(t))c_{ij}(t)$. Why is the social cost? From (35), the marginal utility of consumption exactly reflects the scarcity of providing $c_{ij}(t)$. Thus, the interpretation is that variety assignment is based upon the social benefit $u(c_{ij}(t))$ net of providing that benefit so minus $u'(c_{ij}(t))c_{ij}(t)$.

Given Proposition 1, I can compute the welfare gains from a change in trade costs. I do this by focusing on stationary allocations, so t 's are not relevant. And then study how welfare changes across the two stationary allocations. Here it is of no consequence as there is no moving aggregate state variable in the allocation, so the jump across stationary equilibrium is instantaneous.

Appendix A works out the details, Proposition 2 describes the result.

Proposition 2 (Trade Elasticities and Welfare Gains in the Efficient Allocation) *The elasticity of trade to a change in trade costs between i, j in the efficient allocation is:*

$$\theta_{ij} = -\frac{1}{\sigma_\epsilon} \left[u'(c_{ij})c_{ij} \right]. \quad (37)$$

And the welfare gains from a reduction in trade costs between i, j are

$$\frac{dW}{dd_{ij}/d_{ij}} = \frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{1}{1-\beta} \times \psi_i u'(c_{ij})c_{ij}\pi_{ij}L_i \quad (38)$$

which is the discounted, direct effect from relaxing the resource constraint in (31).

Proposition 2 highlights a couple of things. First, consistent with intuition from Eaton and Kortum's (2002) Ricardian model, the dispersion parameter matters inversely. So if σ_ϵ is small, national varieties are "as if they are near substitutes" and thus trade flows will respond a lot. What is relatively non-standard is that the marginal utility of consumption times consumption shows up here and makes this trade elasticity i, j specific. This is a generic feature of the environment and I discuss this point more below.

⁵A precursor to this result are the migration probabilities derived in Lagakos, Mobarak, and Waugh (2023) in the planing problem for their economy.

The second part of Proposition 2 invokes the envelope theorem and says that the total change in welfare only reflects the direct effect from relaxing the resource constraint, then discounted for the infinite future, hence the $1/(1 - \beta)$ term. Direct effects only matter here since I'm evaluating the change in welfare at the efficient allocation and any benefits of adjusting consumption and choice probabilities are zero—on the margin.

What is the direct effect? It equals the amount being eaten $c_{ij}\pi_{ij}(t)L_i$ times the valuation of the commodity which is the marginal utility of consumption. In other words, the gains from trade come from the destruction of less resources by trade costs, this directly allows for more consumption, and it's converted to utils by the marginal utility of consumption.

This result is reminiscent of Atkeson and Burstein (2010) who make a similar claim in the context of a model with rich firm heterogeneity. More specifically, they argue that the only first order effect lower trade costs have on welfare is the direct consumption effect and that indirect effects are second order. This is similar, but with household heterogeneity, by saying that, in the efficient allocation, the welfare gains are these direct consumption benefits.

As mentioned above, the non-standard thing is that the trade elasticity is i, j specific and reflects the marginal utility of consumption times consumption. Now when preferences are log

$$\theta_{ij} = -\frac{1}{\sigma_\epsilon} \quad \forall \quad i, j, \quad (39)$$

the trade elasticity is *not* i, j specific and it exactly mimics Eaton and Kortum (2002). And it connects with Anderson et al. (1987) and Anderson et al. (1992) (who focus on the log preference case), in that trade here behaves as if there were a representative agent Armington-CES consumer. I discuss this case in the decentralized allocation more below in Section ??

Proposition 2 is useful because it sets a benchmark for thinking about the role that incomplete markets is playing. It also highlights an interesting observation, that outside of log preferences, the random utility model naturally introduces a form of non-homotheticity. And, even in the efficient allocation, this is shaping how aggregate trade is responding to changes in trade costs.

3. Trade Elasticities and the Gains from Trade

This section focuses on the decentralized equilibrium and works towards understanding outcomes like trade elasticities and gains from trade (as in Proposition 2). I show how micro-level decisions shape the aggregate trade elasticity and then the gains from trade and the sources of those gains.

3.1. Trade Elasticities

My definition of the trade elasticity is the partial equilibrium response of imports from j relative to domestic consumption due to a permanent . By partial equilibrium, I mean that wages, interest rates, and the distribution of agents are fixed at their initial equilibrium values. This is consistent with the definition of the trade elasticity in say, Arkolakis et al. (2012) or Simonovska and Waugh (2014). In a sense, the elasticities that I derive are like “short-run” elasticities before aggregates adjust and households respond in-kind. By permanent, I mean that the change in trade costs is for the indefinite future and that households correctly understand this.

Working off of the definition of imports in (17), Proposition 3 defines the aggregate trade elasticity.

Proposition 3 (The H-A Trade Elasticity) *The trade elasticity between country i and country j is:*

$$\theta_{ij} = 1 + \int_a \int_z \left\{ \theta_{ij}(a, z)^I + \theta_{ij}(a, z)^E \right\} \omega_{ij}(a, z) - \left\{ \theta_{ii}(a, z)^I + \theta_{ii}(a, z)^E \right\} \omega_{ii}(a, z) \quad (40)$$

which is the difference between ij and ii expenditure-weighted micro-level elasticities. The micro-level elasticities for households with states a, z are decomposed into an intensive and extensive elasticity

$$\theta_{ij}(a, z)^I = \frac{\partial c_{ij}(a, z)/c_{ij}(a, z)}{\partial d_{ij}/d_{ij}}, \quad \theta_{ij}(a, z)^E = \frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}/d_{ij}},$$

and the expenditure weights are defined as

$$\omega_{ij}(a, z) = \frac{p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z) L_i}{M_{ij}}.$$

Proposition 3 essentially says that the aggregate trade elasticity is an expenditure weighted average of micro-level trade elasticities. And these micro-level trade elasticities are decomposed into two components: an intensive margin trade elasticity $\theta_{ij}(a, z)^I$ reflecting the change in spending by a household on variety from j as trade costs change and an extensive margin trade elasticity $\theta_{ij}(a, z)^E$ reflecting how households substitute across varieties as trade costs change.

Proposition 3 is derived only off the aggregation of imports at the micro level—no market clearing, functional forms, etc. However, by using the households budget constraint and the Type 1 extreme value assumption I can say more about these elasticities and how the household’s consumption-savings problem influences them.

The Intensive Margin Trade Elasticity. By using the households budget constraint in (8) the

intensive margin elasticity becomes:

$$\underbrace{\frac{\partial c_{ij}(a, z)/c_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a, z)^I} = \left[- \frac{\partial g_{ij}(a, z)/p_{ij}c_{ij}(a, z)}{\partial p_{ij}/p_{ij}} - 1 \right] \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}}, \quad (41)$$

where $g_{ij}(a, z)$ is the policy function mapping states into asset holdings next period a' . Equation (41) connects the intensive margin trade elasticity with how a household adjusts its wealth relative to expenditure, given change in the price p_{ij} . So, the way this works is that a reduction in trade costs lowers prices and relaxes the household's budget constraint and then the division of new resources between assets and expenditure determines the intensive margin elasticity.

The feature that's shaping micro responses at the intensive margin is market incompleteness and a households ability to partially insure. In the efficient allocation discussed above, the intensive margin elasticity is minus one as any change in trade costs translates one-for-one into consumption. In the decentralized allocation, the household faces a trade-off about how to reallocate the gains from a reduction in prices between current consumption versus the future. And heterogeneity matters because the trade-off current consumption versus the future is not invariant to a household's state a, z .

The Extensive Margin Trade Elasticity. The Type 1 extreme value distributional assumption connects choice probabilities and a household's problem. As a first step, define the denominator of the choice probability in (11) as:

$$\Phi_i(a, z) = \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right). \quad (42)$$

The elasticity of the choice probability with respect to a change in trade costs is

$$\underbrace{\frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a, z)^E} = - \frac{\partial \Phi_i(a, z)/\Phi_i(a, z)}{\partial d_{ij}/d_{ij}} + \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}}. \quad (43)$$

The first term reflects the fact that the change choice j depends upon a comparison relative to the overall change in the value of options across variety. This is very much similar to how CES models behave except that this term is state a, z specific.

The second term is how the choice specific value function changes with trade costs multiplied by the taste shock parameter. In other words, how elastic or inelastic the extensive margin is depends on how much more valuable choice j becomes. The choice specific value function can

be expanded out as:

$$\frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = \underbrace{-\frac{1}{\sigma_\epsilon} \left[u'(c_{ij}(a, z)) c_{ij}(a, z) \right]}_{\text{micro-analog to (37)}} + \beta \mathbb{E} \frac{1}{\sigma_\epsilon} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}}. \quad (44)$$

The first term in (44) is similar to trade elasticity expression in the efficient allocation of Proposition 2.⁶ The exception is that it is household specific and depends upon their wealth and idiosyncratic productivity. The final term in (44) says that the extensive margin elasticity depends upon how things change as z evolves and through the behavioral response of assets.

To get a better sense of how things work just focus on the first term and differentiate it with respect to assets. The thought experiment here is if a household was a bit wealthier how much more elastic would the household be:

$$\frac{\partial(u'(c_{ij}(a, z)) c_{ij}(a, z))}{\partial a} = u'(c_{ij}(a, z)) \times \text{MPC}_{ij}(a, z) \times \left[-\rho_{ij}(a, z) + 1 \right], \quad (45)$$

where $\text{MPC}_{ij}(a, z)$ is the household's marginal propensity to consume and $\rho_{ij}(a, z)$ is the Arrow-Pratt measure of relative risk aversion.

Constant Relative Risk Aversion (CRRA) preferences makes things super clear. If relative risk aversion is greater than one, this implies that poor, high marginal utility households who are also likely high MPC households are *more elastic relative* to rich households on the extensive margin.⁷ This is the sense in which wealthy or poor households will have systematically different extensive margin elasticities and, like the discussion around the intensive margin elasticity, the households consumption-savings motives play a role.

Figure 1 and 2 illustrates how this works.⁸ Figure 1 plots the absolute value of the trade elasticity (intensive and extensive margin) by household state (assets are on the x-axis, productivity state on the y-axis) and the borrowing constraint ϕ is demarcated in the south-west corner. This shows is how the trade elasticity systematically varies with assets and income: Poor households, especially those near the borrowing constraint, are very price elastic with a trade elasticity of between -10; Richer households are less price elastic with this elasticity declining below -4 (which is the same as $1/\sigma_\epsilon$).

⁶ As I show in the Appendix, a term reflecting the effect of borrowing constraints would also be here, but via envelope theorem type arguments, they zero out for small changes in trade costs.

⁷ In the log preference case (and I work through this case more in depth below), this term becomes zero and the first term in (44) is constant and not varying with wealth.

⁸ In Figures 1 and 2, the key quantitative details are that it's a two symmetric country world with an import share relative to GDP of about 10 percent; u is CRRA with relative risk aversion equal to 1.5; the dispersion parameter σ_ϵ is set to 0.25. The productivity process on z is a mixture of a persistent and transitory process as in which is what is behind the "waves" found in Figures 1 and 2.

Figure 1: Elasticities, $-\theta_{ij}(a, z)$

Figure 2: Trade, $M_{ij}(a, z)/M_{ii}(a, z)$

Because rich and poor households face the same prices, differences in elasticities lead to different trade shares. Figure 2 plots expenditure on the foreign good relative to the home good. First, note that because of trade costs and symmetry across countries, the home good is the relatively cheaper good. Thus, poor, high-price-elastic households spend more on the home good versus the foreign good. In fact for those near the borrowing constraint in this example, it's near zero. Thus, this is a model where micro-level heterogeneity in trade elasticities leads to micro-level variation in expenditure patterns that vary with assets and income.

This pattern of trade elasticities mimics Harrod's (1936) "Law of Diminishing Elasticity of Demand" that says that price sensitivity declines with income; see, e.g., Sangani (2022) who provides evidence in support of this fact and discusses related literature. The evidence in Auer, Burstein, Lein, and Vogel (2022) most closely relates to the patterns in Figure 1 and 2 in that they find (i) household-level import shares systematically differ between rich and poor (ii) poorer households have higher price elasticities and (iii) rich and poor appear to be facing the same relative price changes.

3.2. The Gains from Trade

In this section I compute how social welfare changes to a from a permanent change in trade costs. This section derives these gains across steady states, the idea here is that I'm thinking a situation where the change is small and there is an immediate jump to the new steady state. In the quantitative section, I study transition paths, but the purpose here is to illustrate mechanics and where the gains from trade arise from. Unlike the trade elasticity, I take total derivatives that encompass general equilibrium changes in wages and interest rates.

The analysis proceeds in several steps before stating the main result in Proposition 4. First, I focus only on country i and study a change in trade costs d_{ij} . To simplify the algebra, I choose w_i to be the numeraire and normalize $A_i = 1$. This implies is that p_{ii} equals one and it's derivative with respect to a change in trade costs is zero as it's pinned down by my choice of normalizations.

As in the efficient allocation, I focus on a utilitarian social welfare function:

$$W_i = \int_z \int_a v_i(a, z) L_i \lambda_i(a, z) \quad (46)$$

where $v_i(a, z)$ is a households ex-ante (before preference shocks are realized) value function in country i , with states a, z . The total change in total welfare is

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \int_z \int_a \left\{ \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} + v_i(a, z) \frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}} \right\} L_i \lambda_i(a, z). \quad (47)$$

At a high-level, (47) illustrates that the gains from trade come through two forces. The first component reflects changes in household-level welfare. So conditional on a distribution of households across states, this computes if households are better (or worse!) off from the change. Relative to the efficient allocation this force is always present, however, the planner equalizes things across households such that individual states do not matter and, thus, distributional issues do not matter.

The second component of (47) is about reallocation. It says: take old v 's and compute how the change in the distribution (that arise because of behavioral responses of households) effects social welfare. So does trade make it more or less likely that households are in “good” parts of the distribution. This force is unique to the decentralized allocation and symptomatic of an inefficiency in the initial allocation. In the efficient allocation, the distribution of households is purely technological and the planner always equating things so that on the margin there can not be any gain from shifting households around.

In total, the change in social welfare is then the weighted average of these two forces with the weights being those at the initial distribution.

A key issue in the decentralized allocation is how household-level welfare changes. Here, I make the use of the observation in Equation (14) that the ex-ante value function can be represented in only in terms of home choice i, i values and then recursively pushed forward. In other words, I can compute $\frac{dv_i(a, z)}{dd_{ij}/d_{ij}}$ as if one only consumed the home good for the infinite future. This observation gives rise to the following:

$$\begin{aligned} \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = & -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} + \underbrace{u'(c_{ii}(a, z))a}_{\gamma_{ii}(a, z)} \frac{dR_i}{dd_{ij}/d_{ij}} \\ & + \beta \mathbb{E} \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a', z')/\pi_{ii}(a', z')}{dd_{ij}/d_{ij}} + u'(c_{ii}(a', z')) \frac{dR_i}{dd_{ij}/d_{ij}} a' \dots \text{and into the future.} \right. \end{aligned} \quad (48)$$

Let me walk through the interpretation of each term.⁹ The first term: $-\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}}$ is what I'll call *gains from substitution*. Using logic from Arkolakis et al. (2012), the change in the home choice probability summarizes the benefits of price changes and, hence, it reflects the gains associated with this substitution.

The second term $u'(c_{ii}(a, z))a \frac{dR_i}{dd_{ij}/d_{ij}}$ is what I'll term as *gains to asset trade*. The idea here is that changes in trade costs affect the equilibrium interest rate in the country—even in financial

⁹Similar to the Footnote 6, a general expression has terms reflecting the effect of borrowing constraints. But again, envelope arguments for small changes mean that these terms are zero.

autarky. So through trade induced changes in consumption-savings behavior, a change in trade costs affects net asset demand and, thus, interest rates must adjust to clear the local asset market. An interesting feature of this that it has a strong distributional component in the sense that when interest rates increase households in states of the world who are borrowers would loose and those in the states of the world are lenders would win.

Finally, these three terms repeat themselves into the expected future, appropriately discounted. Proposition 4 summarizes the result below.

Proposition 4 (H-A Welfare Gains from Trade) *The welfare gains from trade are given by*

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \int_z \int_a \left\{ \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} + v_i(a, z) \frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}} \right\} L_i \lambda_i(a, z).$$

which reflects the change in household level gains and how the distribution of households changes. Household level gains are given by

$$\frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = \mathbb{E}_z \sum_{t=0}^{\infty} \beta^t \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}} + u'(c_{ii}(a_t, z_t)) a_t \times \frac{dR_i}{dd_{ij}/d_{ij}} \right\}$$

where each term represents:

- *Gains from substitution:* $-\sigma_\epsilon \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}}.$
- *Gains to asset trade:* $u'(c_{ii}(a_t, z_t)) a_t \times \frac{dR_i}{dd_{ij}/d_{ij}}$

3.3. The Case of log preferences

There is one special case worth working through, it's with log preferences over the physical commodity. This (very common) preference structure leads to an interesting result where micro-level heterogeneity, market incompleteness completely sperate from the trade side of the economy. So in this one case, trade behaves "as if" there were a representative agent Armington-CES consumer and this replicate results similar to Anderson, De Palma, and Thisse (1987) and then the gains from trade take the form in Arkolakis et al. (2012).

Consider the following preference structure:

$$\tilde{u}(c_{ij,t}) = \log(c_{ij,t}) + \epsilon_{j,t}.$$

There is essentially one insight and then everything follows. Examining the problem in (10) and substituting in the households budget constraint from (8), then leads to the observation that the optimal a' conditional on a choice j is **independent** of the price and the choice j .¹⁰

¹⁰A more formal "guess and verify" approach off the Euler equation in 13 leads to the same conclusion and this is verified on the computer as well.

Everything follows from this observation. Because assets don't adjust to changes in prices, from (41) the intensive margin elasticity for i, j is minus one. On the extensive margin, one can show how (43) collapses to $-\frac{1}{\sigma_\epsilon}$ and wealth plays no role (set relative risk aversion to one in (45)). So, at the micro-level, trade elasticities don't vary across households and expenditures are the same for rich and poor (see Figure 6 in the appendix). In aggregate, the trade elasticity is common across country pairs and parameterized by $-\frac{1}{\sigma_\epsilon}$.

Working from Proposition 4 one can see how the gains only depend on aggregates. The reallocation term in (47) is zero because asset holdings don't change. The gains to asset trade are zero because R does not move. Thus, the gains from trade are only about the discounted stream of changes in the home choice probability π_{ii} —which is the same for rich and poor households per the argument in the previous paragraph.

Appendix D works through this logic step-by-step. Below I state the result:

Corollary 1 (Separation of Trade and Micro-Heterogeneity) *In the dynamic, heterogenous agent trade model where preferences are logarithmic over the physical commodity*

$$\tilde{u}(c_{ij,t}) = \log(c_{ij,t}) + \epsilon_{j,t},$$

the trade elasticity is

$$\theta = -\frac{1}{\sigma_\epsilon},$$

and is independent of the household heterogeneity. And the welfare gains from trade are

$$\frac{dW_i}{dd_{ij}/d_{ij}} = -\frac{1}{\theta(1-\beta)} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}.$$

and is (i) independent of the household heterogeneity and (ii) summarized by the trade elasticity and the change in the home choice probability.

To be honest, I found this result surprising. By looking at the choice probabilities in (11) and noting how the value functions determine choices, not period utility functions, one would suspect that the household's income fluctuations problem would shape aggregate trade outcomes. Corollary 1 shows that is not the case but that micro-outcomes and aggregate trade outcomes “separate.”

Essentially, this result takes on the same form as Arkolakis et al. (2012). Trade flows take a constant elasticity form with the trade elasticity pinned down by the dispersion parameter on the trade shocks. And then the total change in welfare is summarized by the trade elasticity and how the share of home purchases changes to any change in trade costs. In the sense that

Arkolakis et al. (2012) result applies to a Armington-CES model, it also connects with Anderson et al. (1987) and Anderson et al. (1992) in that trade here behaves as if there were a representative agent Armington-CES consumer.

With all that said, relative to say Arkolakis et al. (2012) or Anderson et al. (1992), I must emphasize the complexity of the economy at the micro-level for which this result stands. Households are forward looking, face productivity and taste shocks in the presence of incomplete markets and borrowing constraints. Yet, these details don't matter when the magic of log kicks in.

4. Quantitative Analysis

Like a lot of this paper, it's still work in progress. But here is how I'm approaching the problem. At a high-level, I want to put some numbers on things and see how stuff works on. In this sense, the work here is more "quantitative theory" with the goal to deliver a sense of magnitudes.

4.1. Calibration Strategy

I calibrate the model essentially grabbing trade costs and productivity parameters from Eaton and Kortum (2002) for their 19 country data set which is from the 1990s and is comprised of mostly developed countries essentially North America, Western Europe, and Japan. Longer-run the plan is to essentially perform indirect inference where I use the gravity equation as a guide. That is I pick trade costs and productivity parameters so that the gravity regression run on model generated data matches the same moments/coefficients implied by the bilateral trade data.

I focus on the Eaton and Kortum (2002) for data set several reasons. The number of countries of 19 is about the right size (still easy to do on modern desktop) to illustrate how a very rich model like this can work in a multi-country setting. The Eaton and Kortum (2002) data set provides a well defined benchmark disciplined by bilateral trade flows and gravity variables, so it's a nice laboratory to explore new issues within.

The final reason is that Armington structure is probably OK when thinking about older trade patterns where products are highly identified with the nation of origin, like in this data set. When thinking about more recent patterns of trade, and China specifically, this might not be right. Put another way, I'm struggling with how to think about China.

The final parameters to calibrate are relatively straight forward. Taste shock parameter is set so that $1/\sigma_\epsilon = 4.0$. Utility over the physical commodity is CRRA with relative risk aversion 1.5, so just a bit above log and per the discussion above will lead to a pattern (at least qualitatively) or elasticities of substitution across rich and poor households that are consistent with Auer, Burstein, Lein, and Vogel (2022).

Figure 3: Bilateral Trade: Model vs. Data

The final two things to calibrate are the income shock process, borrowing constraint and the discount factor. The shock process is set up to be a mixture of a persistent and transitory component and calibrated as in Krueger, Mitman, and Perri (2016). I use their exact parameter values. Finally the borrowing constraint and discount factor are juggled around so that in the US, the borrowing constraint is about two times median earnings and the equilibrium interest rate in the US is about 2 percent. Because other countries are different in productivity and openness, these values are not the same, but in the same ballpark as the US.

4.2. Preliminary Quantitative Results

Figure 3 provides a sense of model fit with log bilateral trade shares in the model compared to the data. Model fit here means, if you took the parameters from the gravity regression in Eaton and Kortum (2002), what would you get. Here for the most part, things all line up around the 45 degree line. It's not perfect (as would essentially occur in Eaton and Kortum (2002)), but it's pretty good.

The first quantitative experiment I explore are the gains from trade in response to small change in trade costs. Here gains from trade are measured across steady states, transition paths are not taken into account (this is totally feasible, still fixing the code todo so). Small means a global one percent reduction in trade costs. And one reason for the initial focus on a small change

Figure 4: Welfare: U.S. Households, 1% Global Reduction in Trade Costs

regards the first comment— that transitions are not taken into account, but for a small change this should not be a large concern.

Gains from trade here are measured in percent change in welfare, so how many utils changed. A subtle detail is that standard, consumption equivalent unit type measures are more subtle here because they lead to questions about which consumption units (home, foreign), etc. I don't have this sorted out, so this is what I got.

Focusing on what happens with those in the US, Figure 4 plots the welfare gains (vertical axis) versus a households states (productivity z and assets a). So the way to read this is focusing on the upper right-hand corner of Figure 4 say those with the highest assets and income gain in welfare about 0.035 percent given a one percent reduction in trade costs. Next turn your attention in Figure 4 towards the lower left-hand corner. These are those with the lowest assets and income and they **lose** 0.005 percent. Zooming out and looking at how the gains vary with income and assets a message of Figure 4 is that trade is pro-rich.

Where do the losses from trade come from. This is about household net-asset position. Return-

Table 1: Welfare Gains to Reduction in Trade Costs

| A Global 1% Reduction | | |
|-------------------------------|------------------|------------------|
| | Baseline Model | Rep. Agent Model |
| USA | 0.0075 [83] | 0.025 [--] |
| Germany | 0.14 [100] | 0.31 [--] |
| Japan | 0.004 [80] | 0.014 [--] |
| Canada | 0.09 [100] | 0.18 [--] |
| A Global 10% Reduction | | |
| USA | 0.21 [100] | 0.28 [--] |
| Germany | 1.6 [100] | 3.5 [--] |
| Japan | 0.14 [100] | 0.21 [--] |
| Canada | 1.13 [100] | 1.9 [--] |

Note: Numbers in brackets are % of population who gain. Rep. Agent Model uses ACR calculation with trade elasticity = 4.0

ing to Proposition 4, the gains from trade partially depend upon the term:

$$u'(c_{ii}(a_t, z_t))a_t \times \frac{dR_i}{dd_{ij}/d_{ij}} \quad (49)$$

with the important observation being that the sign of this term depends directly upon asset holdings. So if assets are negative and if interest rates increase in response to a reduction in trade costs, this is a force working against any gains from lower prices that net-debtor households might reap.¹¹ Moreover, this force is further amplified because low asset households are likely high marginal utility of consumption households. Finally, if the poor do not gain much from reductions in prices (the first term in Proposition 4) then these asset revaluation effects will dominate. Returning to those in the lower left-hand corner of Figure 4, that's why one sees negative gains from trade.

¹¹The interesting observation is that while assets help households self-insure and inter-temporally transfer resources, there is a sense in that their presence is diminishing the gains from trade for some. That is, if all households were in financial autarky, these issues would not be present.

The top panel of Table 1 provides a sense of how this all plays out across countries for the small, 1 % reduction in trade costs. Of the 19, I chose two relatively large countries (US and Japan) and then two relatively small countries (Canada and Germany). The main number is the average welfare gains and the number in brackets is the percent of the population that gains in each country. Two observations, the large countries on average gain relatively less to the small countries—this is as one should expect. But it's also the large countries that have approximately 20 percent of the population that do not gain from the reduction in trade costs. Per the discussion above, it's the large countries where the real interest rate increased and, hence, their are poor households that start to loose out.

The final column in Table 1 presents the implied gains from an ACR type calculation. These are generally larger, but I suspect that the trade elasticity here is not a fair comparison. When the elasticity is set to $1 \sigma_e$, this is like setting the elasticity towards the rich guy's trade elasticity. Where as the true trade elasticity is something that is less than this. Need to fix.

The bottom panel of Table 1 illustrates this effect for a larger reduction, a 10 % reduction in trade costs. Again, here I'm going to caveat this as this being a place where transition paths would mater, and they are not here.

Two observations stand out. For the larger change in trade costs, everyone in all countries now gains. Interest rates are still rising in the large countries, but this channel is not muted as the gains from lower prices overwhelm these effects for everybody. Second, there are important non-linearities here. In the ACR/Representative Agent benchmark, all numbers essentially increased by a factor of 10. In contrast, in the benchmark economy, large change is just not a scaled up version of the small change with the US and Japan's gains increasing by factors of around 30 relative to the one percent reduction.

5. Conclusion

Appendix

A. The Planning Problem

I focus on a utilitarian social welfare function with Pareto weights that vary across countries:

$$W = \sum_{t=0}^{\infty} \sum_i \int_z \beta^t \psi_i v_i(z, t) L_i \lambda_i(z, t), \quad (50)$$

and here v_i a households utility in country i and ψ_i is the Planners weight on those residing in country i . Now, I'm going to place the social welfare function in sequence space and then unpack the benefits from the preference shock in the following way:

$$W = \sum_{t=0}^{\infty} \sum_i \sum_j \int_z \beta^t \psi_i \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (51)$$

so the inner term is period utility given the associated consumption allocation c_{ij} and then the expected value of the preference shock conditional on the choice probability $\pi_{ij}(z, t)$. This inner term is then weighted by the number of households that receive that utility, i.e. the choice probability times the mass of households with shock z at date t . The sum across j adds up all households in country i and all of this is weighted by the Pareto weight ψ_i . Then the sum across i reflects that this is global welfare.

One more point about the inner term in (51), my claim is that with the Type 1 extreme value shocks:

$$E[\epsilon \mid \pi_{ij}(z, t)] = -\sigma_\epsilon \log \pi_{ij}(z, t) \quad (52)$$

where this is like the “selection correction” where if π becomes smaller, the expected value of the taste shock becomes larger. So only those with the largest relative shocks are chosen and higher utility for those, conditional on being selected, is felt.

Given this formulation, the planner does the following: he chooses consumption and choice probabilities for all country pair combinations, state by state, for the infinite future. The La-

grangian associated with the Planning Problem is:

$$\begin{aligned}
\mathcal{L} = & \sum_{t=0}^{\infty} \sum_i \sum_j \int_z \beta^t \psi_i \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t), \\
& + \sum_{t=0}^{\infty} \sum_i \beta^t \chi_i(t) \left\{ Y_{it} - \sum_j \int_z d_{ji} c_{ji}(z, t) \pi_{ji}(z, t) L_j \lambda_j(z, t) \right\} \\
& + \sum_{t=0}^{\infty} \sum_i \int_z \beta^t \chi_{2i}(z, t) \left\{ 1 - \sum_j \pi_{ij}(z, t) \right\} L_i \lambda_i(z, t),
\end{aligned} \tag{53}$$

where the first term is the objective function; the second line is the resource constraint saying that output from country i must equal the consumption of commodity i globally including the transport costs. Then the third line ensures that choice probabilities are probabilities and sum to one. The final thing I'm doing is that I'm scaling the multipliers by β^t so that the algebra is easier.

Associated with this problem are two first order conditions. The first one is consumption in i with respect to variety j so:

$$\frac{\partial \mathcal{L}}{\partial c_{ij}(z, t)} = \beta^t \psi_i u'(c_{ij}(z, t)) \pi_{ij}(z, t) L_i \lambda_i(z, t) - \beta^t \chi_j(t) d_{ij} \pi_{ij}(z, t) L_i \lambda_i(z, t) = 0 \tag{54}$$

$$\Rightarrow \psi_i u'(c_{ij}(z, t)) = \chi_j(t) d_{ij}, \tag{55}$$

which says that the weighted marginal utility of consumption of (i consuming variety j) should equal it's costs. What is this cost, it's the j 's multiplier adjusted by the trade cost d_{ij} which gives this "price" like interpretation of the multiplier. It's like the shadow value of commodity j which reflects how scarce or not the commodity is then multiplied by the transport costs.

This first order condition has several implications. First, because the right hand side is independent of z , then $\psi_i u'(c_{ij}(z, t)) = \psi_i u'(c_{ij}(z', t)) = \psi_i u'(c_{ij}(t))$ for all z, z' combinations. So within choice, the marginal utility of consumption is equated. Second, across variety choice, within a country (so Pareto weights cancel), the ratio of marginal utility across variety j is:

$$\frac{u'(c_{ij}(t))}{u'(c_{ij'}(t))} = \frac{\chi_j(t) d_{ij}}{\chi_{j'}(t) d_{ij'}} \tag{56}$$

which says that consumption differences relate to the ratio of the multipliers on the resource constraint and the trade costs. This again gives the price like interpretation of the multipliers,

i.e. that differences in the ratio of the marginal utility of consumption reflect relative scarcity or the shadow values. This is essentially a within country Backus and Smith (1993) condition.

The second first order condition is with respect to the choice probabilities. So

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \pi_{ij}(z, t)} &= \beta^t \psi_i \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} L_i \lambda_i(z, t) + \beta^t \psi_i \frac{\partial E[\epsilon \mid \pi_{ij}(z, t)]}{\partial \pi_{ij}} \pi_{ij}(z, t) L_i \lambda_i(z, t) \\ &\quad - \beta^t \chi_j(t) d_{ij} c_{ij}(z, t) L_i \lambda_i(z, t) - \beta^t \chi_{2i}(z, t) L_i \lambda_i(z, t) = 0 \end{aligned} \quad (57)$$

where the first two terms are the marginal, social benefit of changing the choice probabilities. This reflects how utility shifts by adding more households to that choice and then how the expected preference shock changes. The last two terms reflect the costs of changing the choice probabilities which are the resources to provide the additional consumption and the cost of moving households out of other choices which is what the multiplier $\chi_{2i}(z, t)$ represents.

Further simplifying gives:

$$\frac{\partial \mathcal{L}}{\partial \pi_{ij}(z, t)} = \psi_i \left[u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] + \frac{\partial E[\epsilon \mid \pi_{ij}(z, t)]}{\partial \pi_{ij}} \pi_{ij}(z, t) \right] - \chi_j(t) d_{ij} c_{ij}(z, t) - \chi_{2i}(z, t) = 0. \quad (58)$$

Then inserting the observations made above about the Type 1 extreme value distribution and then connecting things with the consumption allocation in 55 one has

$$\psi_i \left[u(c_{ij}(t)) - \sigma_\epsilon \log \pi_{ij}(z, t) - \sigma_\epsilon - u'(c_{ij}(t)) c_{ij}(t) \right] = \chi_{2i}(z, t). \quad (59)$$

Then some algebra gets toward a closed-form expression for the choice probability

$$-\sigma_\epsilon \log \pi_{ij}(z, t) = -u(c_{ij}(t)) + u'(c_{ij}(t)) c_{ij}(t) + \sigma_\epsilon + \chi_{2i}(z, t) \psi_i^{-1}, \quad (60)$$

$$\pi_{ij}(z, t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} - 1 \right) / \exp (\chi_{2i}(z, t) \psi_i^{-1} / \sigma_\epsilon). \quad (61)$$

The choice probabilities must sum to one, so we can set the multiplier so

$$\exp (\chi_{2i}(z, t) \psi_i^{-1} / \sigma_\epsilon) = \sum_{j'} \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} - 1 \right), \quad (62)$$

which implies

$$\chi_{2i}(z, t) = \sigma_\epsilon \psi_i \log \left\{ \sum_{j'} \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t))c_{ij}(t)}{\sigma_\epsilon} - 1 \right) \right\}. \quad (63)$$

Then the choice probability is

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t))c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t))c_{ij'}(t)}{\sigma_\epsilon} \right), \quad (64)$$

which is independent of z and the Pareto weight does not appear. This has the standard Type 1 shape, but the inner most term says that the choice probability should reflect the “net” social benefit of having someone chose that good. The net part is the utility a household receives net of the cost of providing that amount of the consumption. And the cost is, well, c converted into utils which is what the marginal utility bit is doing. Because of that this is all net, the Pareto weight does not directly appear. Given this discussion, the multiplier $\chi_{2i}(t)$ has the interpretation as the expected, net contribution to social welfare of households in country i .

The formal statement is below:

Proposition 5 (The Efficient Allocation) *The allocation that satisfies the Centralized Planning Problem in (33) is:*

1. A consumption allocation satisfying:

$$\psi_i u'(c_{ij}(z, t)) = \chi_j(t) d_{ij} \quad (65)$$

where $\chi_j(t)$ is the shadow price of variety j .

2. The choice probabilities are

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t))c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t))c_{ij'}(t)}{\sigma_\epsilon} \right) \quad (66)$$

and are independent of z because of (65).

The Gains from Trade. Let's compute the social gain to a change in trade costs. First, I going to express social welfare depending directly upon the trade costs d , and then indirectly as the allocations of c and π depend upon d as well.

$$W(d, c_{ij}(d), \pi_{ij}(d)) \quad (67)$$

And then totally differentiate social welfare, so

$$\frac{dW}{dd} = \frac{\partial W}{\partial d} + \frac{\partial W}{\partial c_{ij}(d)} \frac{\partial c_{ij}(d)}{\partial d} + \frac{\partial W}{\partial \pi_{ij}(d)} \frac{\partial \pi_{ij}(d)}{\partial d} \quad (68)$$

and then I invoke the Envelope Theorem. What this means here is that I evaluate this derivative at the optimal allocation. But the optimal allocation is optimal, so on the margin any gain from changing consumption or choice probabilities is zero. So indirect effects (at the optimal allocation) are zero and only direct effects matter. Then computing the direct effect gives

$$\partial W = - \sum_{t=0}^{\infty} \beta^t \chi_j(t) c_{ij}(t) \pi_{ij}(t) L_i \partial d_{ij}, \quad (69)$$

$$= - \sum_{t=0}^{\infty} \beta^t \psi_i u'(c_{ij}(t)) c_{ij}(t) \pi_{ij}(t) L_i \partial d_{ij} / d_{ij}, \quad (70)$$

where the last line inserts the relationship between the multiplier and the marginal utility of consumption in (65). This says that the change in social welfare equals essentially how much the resource constraint is relaxed by the change in trade costs. So it's like the $c_{ij}(t) \pi_{ij}(t) L_i$ is how much stuff people in i get from j and $\partial d_{ij} / d_{ij}$ perturbs it by the percent change in trade costs, then $u'(c_{ij}(t))$ converts it into utils and ψ_i weights it appropriately.

The Elasticity of Trade. This is a bit non-standard from my perspective, but here is my argument. **put in notes on how to do this more directly**

Claim #1: The intensive margin trade elasticity is minus one, i.e. any change in d_{ij} results in a one for one increase, c_{ij} So I don't need to mess with this.

Claim #2: Then all I need to compute is the extensive margin elasticity. So I'm going to note that

$$\frac{\partial \pi_{ij} / \pi_{ij}}{\partial d_{ij} / d_{ij}} = \frac{1}{\sigma_\epsilon} \left[u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij} / d_{ij}} - u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij} / d_{ij}} c_{ij}(t) - u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij} / d_{ij}} \right] - \frac{\partial \Phi_i(t) / \Phi_i(t)}{\partial d_{ij} / d_{ij}} \quad (71)$$

$$= \frac{-1}{\sigma_\epsilon} \left[u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij} / d_{ij}} c_{ij}(t) \right] - \frac{\partial \Phi_i(t) / \Phi_i(t)}{\partial d_{ij} / d_{ij}} \quad (72)$$

which the first line follows from the quotient rule and where $\Phi_i(t)$ is the part of the denominator in the choice probability. Recall the trade elasticity is relative to own trade so

$$\frac{\partial \pi_{ii} / \pi_{ii}}{\partial d_{ij} / d_{ij}} = - \frac{\partial \Phi_i(t) / \Phi_i(t)}{\partial d_{ij} / d_{ij}} \quad (73)$$

Then using my H-A Trade Elasticity formula, I have that:

$$\theta_{ij} = 1 + \theta_{ij}^I + \theta_{ij}^E = 1 + -1 + \frac{-1}{\sigma_\epsilon} \left[u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} c_{ij}(t) \right] \quad (74)$$

Then here is what is interesting. I mention this fact below

$$u'(c_{ij}(t)) = \chi_j(t) d_{ij} \Rightarrow u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} = \chi_j(t) d_{ij} \quad (75)$$

so this means that the trade elasticity is:

$$\theta_{ij} = \frac{-1}{\sigma_\epsilon} \left[u'(c_{ij}(t)) c_{ij}(t) \right] \quad (76)$$

where here you can already see the “standard result” with log preferences that the trade elasticity is independent of i, j and is the one over the dispersion parameter like in Eaton and Kortum (2002). The next interesting piece is if this is combined with the gains from trade formula which is (in a stationary setting)

$$\frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{\sigma_\epsilon \theta_{ij} \pi_{ij} L_i}{1 - \beta}, \quad (77)$$

in other words, the gains from trade are how many people are buying i, j times the trade elasticity, discounted for the indefinite future.

Proposition 6 (Trade Elasticities and Welfare Gains in the Efficient Allocation) *The elasticity of trade to a change in trade costs between i, j in the efficient allocation is:*

$$\theta_{ij} = -\frac{1}{\sigma_\epsilon} \left[u'(c_{ij}) c_{ij} \right]. \quad (78)$$

And the welfare gains from a reduction in trade costs between i, j are

$$\frac{dW}{dd_{ij}/d_{ij}} = \frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{1}{1 - \beta} \times \psi_i u'(c_{ij}) c_{ij} \pi_{ij} L_i \quad (79)$$

which is the discounted, direct effect from relaxing the resource constraint in (31).

The one issue with this last result is that it's a bit opaque relative to the other welfare results that I derived. Let me connect them. So per the arguments above, I can write the ex-ante utility and inserting the allocations associated with the planner as

$$v_i(t) = -\sigma_\epsilon \log \pi_{ii} + u(c_{ii}(t)) \quad (80)$$

and then

$$\frac{\partial v_i(t)}{\partial d_{ij}/d_{ij}} = -\sigma_\epsilon \frac{\partial \pi_{ii}/\pi_{ii}}{\partial d_{ij}/d_{ij}} \quad (81)$$

so the gains only work through the home share. Now this elasticity is

$$\frac{\partial \pi_{ii}/\pi_{ii}}{\partial d_{ij}/d_{ij}} = -\frac{\pi_{ij}}{\sigma_\epsilon} \left\{ u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} - \left[u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} + u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} c_{ij}(t) \right] \right\} \quad (82)$$

$$= -\frac{\pi_{ij}}{\sigma_\epsilon} u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} c_{ij}(t) \quad (83)$$

Then notice the following from the consumption allocation that

$$u'(c_{ij}(t)) = \chi_j(t) d_{ij} \Rightarrow u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} = \chi_j(t) d_{ij} \quad (84)$$

where I'm just differentiating both sides by d_{ij} and then dividing through by d to make an elasticity. Then this implies that

$$\frac{\partial \pi_{ii}(t)/\pi_{ii}(t)}{\partial d_{ij}/d_{ij}} = \frac{\pi_{ij}(t)}{\sigma_\epsilon} u'(c_{ij}(t)) c_{ij}(t) \quad (85)$$

and then

$$\frac{\partial v_i(t)}{\partial d_{ij}/d_{ij}} = \pi_{ij} u'(c_{ij}(t)) c_{ij}(t) \quad (86)$$

which means that the total change in social welfare equals

$$\frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{\partial W_i}{\partial d_{ij}/d_{ij}} = \frac{1}{1-\beta} \times u'(c_{ij}(t)) c_{ij}(t) \pi_{ij}(t) L_i \quad (87)$$

and I'm done.

Computing the Efficient Allocation. Here I talk through an algorithm to actually compute the efficient allocation in a stationary setting.

1. First guess a level of home consumption c_{ii} for each country i .
2. From first part of the efficient allocation, we can recover the country specific multipliers from

$$u'(c_{ii}) = \chi_i \quad (88)$$

and then recover the consumption levels for every country i, j pairs

$$c_{ij} = u'^{-1}(\chi_j d_{ij}) \quad (89)$$

so what we have is now an allocation of consumption that satisfies the first part of 5.

3. Construct choice probabilities from (66)
4. Check if the resource constraint holds. Specifically

$$Y_i - \sum_j d_{ji} c_{ji} \pi_{ji} L_j = 0 \quad (90)$$

where notice that Y_i is predetermined given that there is no labor supply or capital. If this condition is not satisfied, for every country, then update the guess on consumption.

5. Once this is converged, we can construct trade flows in the following way:

$$\frac{M_{ij}}{M_{ii}} = \frac{u'(c_{jj}) d_{ij} c_{ij} \pi_{ij} L_i}{u'(c_{ii}) c_{ii} \pi_{ii} L_i} \quad (91)$$

where I'm using the observation that $u'(c_{ii}) = \chi_i$ and is the shadow price of variety i , not inclusive of the trade costs. So this is the as if value of imports in country i from country j relative to home trade. And then from here one can construct a "trade wedge" which is the ratio between the volume of trade in efficient allocation relative to the volume of trade in the decentralized allocation.

B. The H-A Trade Elasticity

My definition of the trade elasticity is the partial equilibrium response of imports from j relative to domestic consumption due to a permanent change in trade costs between steady states. By partial equilibrium, I mean that wages and interest rates are fixed at their initial equilibrium values. By permanent, I work this out under the heuristic of a “steady-state to steady-state comparison” where I factor in how the stationary distribution changes due to changes in behavior. This definition is consistent with the broad terminology used in the trade literature, e.g. Arkolakis et al. (2012) and Simonovska and Waugh (2014). Consistent with this discussion and the notation below, I compute the partial derivatives (not total) of objects with respect to trade costs.

Mathematically, the trade elasticity equals the difference between the elasticities for how trade between i and j change minus how home trade changes:

$$\frac{\partial(M_{ij}/M_{ii})}{\partial d_{ij}} \times \frac{d_{ij}}{(M_{ij}/M_{ii})} = \frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}} - \frac{\partial M_{ii}/M_{ii}}{\partial d_{ij}/d_{ij}}. \quad (92)$$

The change in imports between i and j with respect to a change in trade costs is:

$$\frac{\partial M_{ij}}{\partial d_{ij}} = \int_{a,z} \left\{ \frac{\partial p_{ij}}{\partial d_{ij}} c_{ij}(a, z) \pi_{ij}(a, z) + \frac{\partial c_{ij}(a, z)}{\partial d_{ij}} p_{ij} \pi_{ij}(a, z) + \frac{\partial \pi_{ij}(a, z)}{\partial d_{ij}} p_{ij} c_{ij}(a, z) \right\} L_i \lambda_i(a, z). \quad (93)$$

Divide the stuff on the inside of the brackets by household level imports $p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z)$ and multiply on the outside giving,

$$\frac{\partial M_{ij}}{\partial d_{ij}} = \int_{a,z} \left\{ \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}} + \frac{\partial c_{ij}(a, z)/c_{ij}(a, z)}{\partial d_{ij}} + \frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}} \right\} p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) L_i \lambda_i(a, z). \quad (94)$$

Define the following weight which is the share of goods that those with states a, z account for in total expenditures from j as

$$\omega_{ij}(a, z) = \frac{p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) L_i \lambda_i(a, z)}{M_{ij}}. \quad (95)$$

where the sum of $\omega_{ij}(a, z)$ over states a, z equals one. This gives a nice expression for the import elasticity

$$\frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}} = 1 + \sum_{a,z} \left\{ \underbrace{\frac{\partial c_{ij}(a, z)/c_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^I} + \underbrace{\frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^E} \right\} \omega_{ij}(a, z) \quad (96)$$

or more succinctly as

$$\frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}} = 1 + \sum_{a,z} \left\{ \theta_{ij}(a,z)^I + \theta_{ij}(a,z)^E \right\} \omega_{ij}(a,z) \quad (97)$$

where the elasticity of aggregate imports into i from j is a weighted average of three different micro-level elasticities.

Note that the one out front arises from complete pass-through of changes in trade costs to changes in prices. And that this one only shows up in for the $\frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}}$ elasticity as there is no direct effect on prices, p_{ii} .

Given the expression in (92), Proposition 7 follows:

Proposition 7 (The H-A Trade Elasticity) *The trade elasticity between country i and country j is:*

$$\theta_{ij} = 1 + \int_a \int_z \left\{ \theta_{ij}(a,z)^I + \theta_{ij}(a,z)^E \right\} \omega_{ij}(a,z) - \left\{ \theta_{ii}(a,z)^I + \theta_{ii}(a,z)^E \right\} \omega_{ii}(a,z) \quad (98)$$

which is the difference in expenditure weighted micro-level elasticities. The micro-level elasticities for households with states a, z are decomposed into an intensive and extensive margin elasticity

$$\theta_{ij}(a,z)^I = \frac{\partial c_{ij}(a,z)/c_{ij}(a,z)}{\partial d_{ij}/d_{ij}}, \quad \theta_{ij}(a,z)^E = \frac{\partial \pi_{ij}(a,z)/\pi_{ij}(a,z)}{\partial d_{ij}/d_{ij}},$$

and the expenditure weights are defined as

$$\omega_{ij}(a,z) = \frac{p_{ij} c_{ij}(a,z) \pi_{ij}(a,z) \lambda_i(a,z)}{M_{ij}}$$

By using the households budget constraint one can express the intensive margin elasticity as

$$\underbrace{\frac{\partial c_{ij}(a,z)/c_{ij}(a,z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^I} = \left[- \frac{\partial g_{ij}(a,z)/p_{ij} c_{ij}(a,z)}{\partial p_{ij}/p_{ij}} - 1 \right] \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}}, \quad (99)$$

where recall that $g_{ij}(a,z)$ is the policy function mapping states into asset holdings next period a' . What this means is that the intensive margin elasticity is about a households consumption-savings behavior, i.e., how a household adjusts assets given a change in the price p_{ij} .

The Type 1 extreme value assumption allows for a characterization of how the choice probabilities change. As a first step, define the denominator of the choice probability as:

$$\Phi_i(a,z) = \sum_{j'} \exp \left(\frac{v_{ij'}(a,z)}{\sigma_\epsilon} \right). \quad (100)$$

The elasticity of the choice probability with respect to a change in trade costs is

$$\underbrace{\frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a, z)^E} = \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i(a, z)/\Phi_i(a, z)}{\partial d_{ij}/d_{ij}}. \quad (101)$$

Now interestingly, I can say more about the value function part

$$\frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = -u'(c_{ij}(a, z))c_{ij}(a, z) + \left[-\frac{u'(c_{ij}(a, z))}{p_{ij}} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \right] + \beta \mathbb{E} \left\{ \frac{\partial v}{\partial a'} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} \right. \quad (102)$$

$$\left. + \frac{\partial v(g_{ij}(a, z), z')}{\partial p_{ij}/p_{ij}} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} \right\} \quad (103)$$

which can then be further expressed using the Euler equation below as

$$\frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = -u'(c_{ij}(a, z))c_{ij}(a, z) \quad (104)$$

$$+ \left\{ -\frac{u'(c_{ij}(a, z))}{p_{ij}} + \beta \mathbb{E} \left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z'))R \right] \right\} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \quad (105)$$

$$+ \beta \mathbb{E} \left\{ \frac{\partial v_i(a', z')}{\partial p_{ij}/p_{ij}} \right\} \quad (106)$$

The term reflecting the Euler equation should be zero for small changes. See the discussion below around the welfare gains calculation.

I can then connect the first term with things like the relative risk aversion and the marginal propensity to consume. The thought experiment here is if a household was a bit wealthier what would the effect be on the $u'(c_{ij}(a, z))c_{ij}(a, z)$ and hence how one component of the extensive

margin elasticity changes:

$$\frac{\partial(u'(c_{ij}(a, z))c_{ij}(a, z))}{\partial a} = u''(c_{ij}(a, z)) \frac{\partial c_{ij}}{\partial a} c_{ij}(a, z) + u'(c_{ij}(a, z)) \frac{\partial c_{ij}}{\partial a} \quad (107)$$

$$= \frac{\partial c_{ij}}{\partial a} \left[u''(c_{ij}(a, z))c_{ij}(a, z) + u'(c_{ij}(a, z)) \right] \quad (108)$$

$$= u'(c_{ij}(a, z)) \times \text{MPC}_{ij}(a, z) \times \left[-\rho_{ij}(a, z) + 1 \right]. \quad (109)$$

And just to emphasize how this works, it's a derivative of $u'(c_{ij}(a, z))c_{ij}(a, z)$. So as assets go up, with $\rho > 1$ this implies that $u'(c_{ij}(a, z))c_{ij}(a, z)$ goes down! And this is a force for things to be less elastic for rich guys. As assets go down, this implies that $u'(c_{ij}(a, z))c_{ij}(a, z)$ goes up, and this is a force for poor guys to be more elastic.

C. The Welfare Gains from Trade

This section derives the gains from a permanent change in trade costs, across steady states. Like the discussion above, the idea here is that I'm thinking a situation where the change is small and there is an immediate jump to the new steady state. Unlike the trade elasticity, I'm going to take total derivatives that will encompass general equilibrium changes in wages and interest rates.

The analysis proceeds in several steps.

First, I'm going to focus on country i and study a change in trade costs d_{ij} . To simplify the algebra, I'm going to choose w_i to be the numeraire. Then I'm going to normalize $A_i = 1$. What this implies is that $p_{ii} = \frac{w_i}{A_i}$ equals one and it's derivative with respect to things is zero.

Second, To compute how social welfare changes, I focus on a utilitarian social welfare function (Pareto weights across households, within a country, are the same):

$$W_i = \int_a \int_z v_i(a, z) \lambda_i(a, z) \quad (110)$$

Then the total change in total welfare is

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \int_a \int_z \left\{ \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} + v_i(a, z) \frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}} \right\} \lambda_i(a, z). \quad (111)$$

What illustrates is that the gains from trade come through two forces. The first component reflects changes in household-level welfare. So conditional on a distribution of households

across states, are households better or worse off. The second component is about reallocation, i.e., if—at the old v 's—does the distribution change so that social welfare gets better or worse. The change in social welfare is then the weighted average of these two forces with the weights being those at the initial distribution.

How does household-level welfare change? With the Type 1 extreme value distribution some progress can be made in several steps. First, notice that I can express everything relative to the home country i . Recall that the value function (with the expectation taken over the different preference shocks) is

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) \right\}, \quad (112)$$

and then I'm going to make the observation that I can substitute out the sum part (112 with the exp of the home value function relative to the micro-level “home choice” so

$$\pi_{ii}(a, z) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right), \quad (113)$$

$$\pi_{ii}(a, z) \times \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right), \quad (114)$$

$$\sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right) / \pi_{ii}(a, z). \quad (115)$$

Then substituting (115) into the value function in (112) gives:

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \frac{\exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right)}{\pi_{ii}(a, z)} \right\} \quad (116)$$

and recall that the home choice value function is

$$v_{ii}(a, z) = u(c_{ii}(a, z)) + \beta \mathbb{E} v_i(g_{ii}(a, z), z) \quad (117)$$

where the expectation operator is over the z s and the v_i is the same value function as in (112) so the taste shocks are integrated out. Taking logs and exp's of (116) allows for the v_i value function to be represented as

$$v_i(a, z) = -\sigma_\epsilon \log \pi_{ii}(a, z) + u(c_{ii}(a, z)) + \beta \mathbb{E} v_i(g_{ii}(a, z), z). \quad (118)$$

The key innovation here is that now everything is written with respect to the home choice. Where are the taste shocks? What is going on is that the home choice π_{ii} summarizes the expected value of those shocks and their benefits. No need to explicitly carry around the v_{ij} s. This is essentially the dynamic analog to Equation (15), Footnote 42 of Eaton and Kortum (2002) and Arkolakis et al. (2012) and I explicitly show this in the example section below.

Now the strategy is to totally differentiate (118) with respect to trade costs and use the recursive structure to iterate forward and construct the change across time. One more detail, to facilitate interpretation, it will be useful to compute the Euler equation associated with asset holdings when the borrowing constraint does not bind. This euler equation is:

$$-u'(c_{ii}(a, z)) = \beta \mathbb{E} \left\{ -\sigma_\epsilon \frac{\partial \pi_{ii}(a', z') / \pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right\}, \quad (119)$$

which says that the agent should be indifferent between the marginal utility of consumption forgone to hold some more assets and two components (i) the benefit from how a change in assets changes in their variety choice and (ii) the direct benefit of the returns on the assets evaluated at the marginal utility of consumption.

Redo. Digression on chain rule. I'm going to

$$v(a', z') = v(g(a, z, d), z') \quad (120)$$

where I substitute in the policy function for a' . Then first term inside indicates that v depends upon the choice of a' and this works through the policy function. And the dependence of v on d (and not through assets) is implicit. Then the total derivative of this is

$$\frac{dv(g(a, z, d), z')}{dd} = \frac{\partial v}{\partial a'} \frac{dg}{dd} + \frac{\partial v(\overline{g(a, z, d)}, z')}{\partial d} \quad (121)$$

So the first term is the partial change of v with respect to a' times how the policy function totally changes with respect to d . The second term is the partial change of v with respect to d , **holding fixed assets** at their chosen level. That's why I'm emphasizing the bar on top. Now what is confusing to me is that this has partial, not total derivatives. But this term is mathematically the same as

$$\frac{\partial v(\overline{g(a, z, d)}, z')}{\partial d} = \frac{dv(a', z')}{dd} \quad (122)$$

where the RHS is the total derivative of v treating a' as a parameter. In other words, the LHS says, how does v change (everything else) holding fixed assets. The RHS says how does ev-

everything else change holding fixed assets. There the same. And the RHS is the value function evaluated at the new states a', z' .

Totally differentiating the value function gives

$$\frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} + u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a - u'(c_{ii}(a, z)) \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} + \beta E \frac{dv_i(g_{ii}(a, z), z')}{dd_{ij}/d_{ij}} \quad (123)$$

Then the derivative of the continuation value function is:

$$\frac{dv_i(g(a, z), z')}{dd_{ij}/d_{ij}} = \underbrace{\left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right]}_{\frac{\partial v_i(g_{ii}(a, z), z')}{\partial a}} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} + \quad (124)$$

$$-\sigma_\epsilon \frac{d\pi_{ii}(a', z')/\pi_{ii}(a', z')}{dd_{ij}/d_{ij}} + u'(c_{ii}(a', z')) \frac{dR}{dd_{ij}/d_{ij}} a' - u'(c_{ii}(a', z')) \frac{dg_{ii}(a', z')}{dd_{ij}/d_{ij}} + \beta E \frac{dv_i(g_{ii}(a', z'), z'')}{dd_{ij}/d_{ij}} \quad (125)$$

And now combine and collect terms so

$$\frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} \quad (126)$$

$$+ \underbrace{u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a}_{\gamma_{ii}(a, z)} \quad (127)$$

$$+ \underbrace{\left\{ -u'(c_{ii}(a, z)) + \beta E \left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right] \right\} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}}}_{\delta_{ii}(a, z)} \quad (128)$$

$$+ \beta E \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} + u'(c_{ii}(a', z')) \frac{dR}{dd_{ij}/d_{ij}} a' \dots \right. \quad (129)$$

Let me walk through the interpretation of each term:

- $-\sigma_\epsilon \frac{d\pi_{ii}(a,z)/\pi_{ii}(a,z)}{dd_{ij}/d_{ij}}$ is the standard gains from trade term reflecting the idea that gains work through changes in expenditures across different varieties. With static logit, this is exactly the ACR formula.
- $u'(c_{ii}(a,z)) \frac{\partial R}{\partial d_{ij}/d_{ij}} a$ or what I'm labeling as $\gamma_{ii}(a,z)$ is what I would call how trade facilitates more asset trade. I think as trade costs decline the amount of resources available for asset trade expands and this changes the interest rate. Which way does it go?
- The third term which I'm labeling as $\delta_{ii}(a,z)$ is the Euler equation for assets. Honestly, it's pretty cool the way this shows up here. But it should also zero out through some basic arguments. Let me expand on this.

The idea is that if the household is unconstrained, then this term is zero as there is no gain through changes in asset behavior. Asset holdings are already chosen optimally so that margins are equated, thus, on the margin any benefit of lower trade costs on changes in asset behavior is zero. Essentially an application of the Envelope Theorem.

Now in this economy, this term may not be zero because of borrowing constrained households, thus this term is positive. However, notice how the outside brackets is multiplied by the change in the asset policy function. Again, this is super cool. What this picks up is that if the household is constrained, then assets can't change so the outside term is zero and, thus, overall the second term is zero.

Final point, then the only people that benefit and contribute to social welfare through these effects are those on the margin between constrained and not-constrained. But if they are on the margin between being constrained and not-constrained, then they are on their euler equation. More formally, these agents are those where, from the Generalized Euler equation in (155), both terms under the max operator are equated, so

$$\beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right] = u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \quad (130)$$

- The final term is about this continuing on into the infinite future.

Iterating on (129) into the future, the gains from trade for a household with states a, z today are

$$\frac{\partial v_i(a, z)}{\partial d_{ij}/d_{ij}} = \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}} + \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\} \quad (131)$$

Where the first component is the expected discounted gains from substitution, gains from asset trade and the relaxation of borrowing constraints. Combining (131) and (111) yields the following proposition for the gains from trade

Proposition 8 (The Welfare Gains from Trade) *The welfare gains from trade are given by*

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \int_a \int_z \left\{ \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} + v_i(a, z) \frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}} \right\} \lambda_i(a, z).$$

which reflects the change in household level gains and how the distribution of households changes. Household level gains are given by

$$\frac{\partial v_i(a, z)}{\partial d_{ij}/d_{ij}} = \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ -\sigma_{\epsilon} \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}} + \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\}$$

where each term represents:

- *Gains from substitution:* $-\sigma_{\epsilon} \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}}.$
- *Gains from asset trade:* $\gamma_{ij}(a, z) = u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a$
- *Gains from relaxing borrowing constraints:*

$$\delta_{ii}(a, z) = \left\{ -u'(c_{ii}(a, z)) + \beta \mathbb{E} \left[-\sigma_{\epsilon} \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right] \right\} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} = 0$$

which are equal to zero for small changes.

Proposition 8 nests several interesting cases that connect with the literature and further illustrate the mechanics.

D. Log Preferences

This example is interesting because it retains an aggregate constant trade elasticity, but at the micro-level it is not quite with things canceling in a way during aggregation. Second, the welfare gains from trade formula looks like ACR kind of thing. Because this is a bit more involved I'm going to be super systematic about this.

Step 1: Individual Choices. With log preferences the j choice value function is

$$v_{ij}(a, z) = \max_{a' \in \mathcal{A}} \left\{ \log \left(\frac{Ra + wz - a'}{p_{ij}} \right) + \beta \mathbb{E}[v_i(a', z')] \right\} \quad (132)$$

which is then

$$v_{ij}(a, z) = \max_{a' \in \mathcal{A}} \left\{ \log(Ra + wz - a') + \beta \mathbb{E}[v_i(a', z')] \right\} - \log p_{ij} \quad (133)$$

which then leads to the observation that the optimal a' conditional on a choice j is **independent** of the price and the choice j . So what is going on is if you consume an expensive or cheap good,

then consumption simply scales up or down so that assets next period are exactly the same. This observation has the implication that expenditures on consumption are the same across choices. Compare households expenditures with the same state a, z but different choices. Equation (133) implies

$$p_{ij}c_{ij}(a, z) = p_{ii}c_{ii}(a, z) \quad (134)$$

so within states, people always spend the same amount. This fact will be useful below.

Finally, this observation implies that the choice probabilities are independent of the state only prices matter so

$$\pi_{ij}(a, z) = \exp\left(\frac{v_{ij}(a, z)}{\sigma_\epsilon}\right) / \sum_{j'} \exp\left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon}\right) \quad (135)$$

$$\pi_{ij} = \exp\left(\frac{-\log p_{ij}}{\sigma_\epsilon}\right) / \sum_{j'} \exp\left(\frac{-\log p_{ij'}}{\sigma_\epsilon}\right) \quad (136)$$

which is exactly the same as discussed above in the static model. These observations are all consistent with the Generalized Euler Equation below. To see this

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \max \left\{ \beta R_i \mathbb{E} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right], u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \right\} \quad (137)$$

and then impose log preferences and notice that

$$(Ra + wz - a')^{-1} = \max \left\{ \beta R \mathbb{E} \left[\sum_{j'} \pi_{ij}(a', z') (Ra' + wz - a'')^{-1} \right], (Ra + w - \phi_i)^{-1} \right\} \quad (138)$$

and then because the term multiplying the π_{ij} 's does not depend upon j it can be pulled out and

$$(Ra + wz - a')^{-1} = \max \left\{ \beta R \mathbb{E} (Ra' + wz' - a'')^{-1}, (Ra + w - \phi_i)^{-1} \right\} \quad (139)$$

and thus the asset choice is independent from the variety choice j .

Step 2: Micro Trade Elasticities. I'm going to be super systematic about this:

- Starting with (99) and because the asset choice is independent of prices, the intensive margin elasticity $\theta_{ij}(a, z)^I$ is -1 and $\theta_{ii}(a, z)^I$ is zero as there are no partial effects on prices in ii .

- The extensive margin elasticity is:

$$\theta_{ij}(a, z)^E = \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (140)$$

$$= -\frac{1}{\sigma_\epsilon} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i(z)/\Phi_i(z)}{\partial d_{ij}/d_{ij}} \quad (141)$$

$$= -\frac{1}{\sigma_\epsilon} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (142)$$

where the first line removes the a, z indexing of Φ_i because they don't shape the choice probabilities. The next line then partially differentiates the value function with respect to the change in trade costs and I'm exploiting how with log preferences one can pull out the price term. And then the final line notes that the price elasticity is minus one. One more fact that:

$$\theta_{ii}(a, z)^E = \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (143)$$

where a key thing to notice is that the i, i elasticity is the same as the second and third terms above in (142).

It's worth emphasizing that the micro trade elasticities are **not** constant across states a, z . Unlike the static model with log preferences, they are varying by income and assets as the derivative of the value function is showing up. But what **is** occurring is that across different destinations, within states, they are varying in the same exact way. This is one aspect of this case that facilitates aggregation. However, the necessary aspect is that the expenditure weights work out in the right way, I show this next.

Step 3: Expenditure Weights. Recall that the micro level trade elasticities when aggregated are weighted by

$$\omega_{ij}(a, z) = \frac{p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z)}{M_{ij}}. \quad (144)$$

and note that we can relabel $p_{ij} c_{ij}(a, z) = x(a, z)$ given (134), that expenditures are independent

of the destination. With the choice probabilities independent of a, z the weights become

$$\omega_{ij}(a, z) = \frac{x(a, z)\pi_{ij}\lambda_i(a, z)}{\sum_{a, z} x(a, z)\pi_{ij}\lambda_i(a, z)}, \quad (145)$$

$$= \frac{x(a, z)\lambda_i(a, z)}{\sum_{a, z} x(a, z)\lambda_i(a, z)} \quad (146)$$

which are independent of source j . This is the second important observation that will facilitate aggregation.

Step 4: The Trade Elasticity. Now just mechanically follow Proposition 3:

$$\begin{aligned} \theta_{ij} &= 1 + \int_{a, z} \left\{ -1 + -\frac{1}{\sigma_\epsilon} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \right\} \omega_i(a, z) \\ &\quad - \int_{a, z} \left\{ \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \right\} \omega_i(a, z) \\ &= -\frac{1}{\sigma_\epsilon} \end{aligned} \quad (147)$$

where the last line follows because the a, z terms in the micro level trade elasticities exactly cancel given that expenditure weights are source independent. And the aggregate trade elasticity is constant and parameterized by the dispersion in tastes.

Step 5: The Grains From Trade. Then from here I can just follow Proposition 4. First the individual gains are

$$\frac{\partial v_i(a, z)}{\partial d_{ij}/d_{ij}} = \underbrace{-\frac{1}{\theta(1-\beta)} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}}_{ACR} + \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\}$$

where the first term is exactly in the static model except for the discounting bit. But what facilitates this is that the choice probabilities are independent of a, z and it can be pulled out of the expected discounted sum stuff. Then the subsequent terms take a slightly cleaner form:

- Gains from asset trade: $\gamma_{ij}(a, z) = \frac{dR}{dd_{ij}/d_{ij}} \frac{a}{c_{ii}(a, z)}$

Step 6: Assets don't matter. Claim is that because the asset policy function g is independent of the price of varieties, then any change in trade costs will not affect R and thus the total derivative $\frac{dR}{dd_{ij}/d_{ij}}$ equals zero and then the total derivative $\frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}}$ on the asset policy function is zero. And then $\frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}}$ is zero as well.

Corollary 2 (Separation of Trade and Heterogeneity) *In the dynamic, heterogenous agent trade model where preferences are logarithmic over the physical commodity*

$$\tilde{u}(c_{ij,t}) = \log(c_{ij,t}) + \epsilon_{j,t},$$

the trade elasticity is

$$\theta = -\frac{1}{\sigma_\epsilon},$$

and is independent of the household heterogeneity. Ant the welfare gains from trade are

$$\frac{dW_i}{dd_{ij}/d_{ij}} = -\frac{1}{\theta(1-\beta)} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}.$$

and is (i) independent of the household heterogeneity and (ii) summarized by the trade elasticity and the change in the home choice probability.

To visualize some of this on the computer, Figures (5) and (6) plot elasticities by state and trade shares. No short-cuts are involved in this calculation, the same exact algorithm is applied. The result is apparent, with log preference, trade elasticities and trade shares become independent of what is going on with the household and, thus, there is pure separation between them.

Figure 5: Log Preferences, Trade Elasticities, $-\theta_{ij}(a, z)$

Figure 6: Log Preferences, Trade, $M_{ij}(a, z)/M_{ii}(a, z)$

E. Appendix: Endogenous Grid Method

First, I'm going to derive the Euler equation for this model. I'll abstract from the situation in which the HH is at the borrowing constraint.

Focus on the within a variety choice component, the households value function can be written as:

$$v_{ij}(a, z) = \max_{a'} u \left(\frac{R_i a + w_i z - a'}{p_{ij}} \right) + \beta E v(a', z') \quad (148)$$

then the first order condition associated with this problem is:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \beta E \frac{\partial v(a', z')}{\partial a'} \quad (149)$$

which is saying that, conditional on a variety choice the left hand side is the loss in consumption units which is $1/p_{ij}$ evaluated at the marginal utility of consumption and then this is set equal to the marginal gain from saving a bit more which is how the value function changes with respect to asset holdings. Now we can arrive at the $\frac{\partial v(a', z')}{\partial a'}$ in the following way, so start from the log-sum expression for the expected value function

$$\mathbb{E}_\epsilon v(a', z') = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right) \right\} \quad (150)$$

and then differentiate this with respect to asset holdings which gives:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \left(\frac{\sigma_\epsilon}{\sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right)} \right) \left[\sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right) \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a', z')}{\partial a'} \right] \quad (151)$$

Then if you look at this carefully and notices how the choice probabilities from (11) are embedded in here, we have:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \sum_{j'} \pi_{ij}(a', z) \frac{\partial v_{ij}(a', z')}{\partial a'} \quad (152)$$

and then we can just apply the Envelop theorem to the value functions associated with the discrete choices across the options:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \sum_{j'} \pi_{ij}(a', z) \frac{u'(c_{ij}(a', z')) R_i}{p_{ij}} \quad (153)$$

So then putting everything together we have:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right] \quad (154)$$

where this has a very natural form: you set the marginal utility of consumption today equal to the marginal utility of consumption tomorrow adjusted by the return on delaying consumption, and the expected value of the marginal utility of consumption which reflects how the uncertainty over both ones' preference over different varieties and shocks to efficiency units. Taking into account the borrowing constraint then gives the generalized Euler equation from which the endogenous grid method will exploit:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \max \left\{ \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right], u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \right\} \quad (155)$$

5.1. EGM-Discrete Choice Algorithm

Here is a proposed approach. This focuses on just the consumer side in one country i .

0. Set up an asset grid as usual. Then guess (i) a consumption function $g_{c,ij}(a, z)$ for each a , z , and product choice j and (ii) choice specific value function $v_{ij}(a, z)$.
1. Compute the choice probabilities from (11) for each (a, z) combination, given the guessed value functions.
1. Given the consumption function and choice probabilities compute the RHS of (13) first.
2. Then invert to find the new updated consumption choice so

$$c_{ij}(\tilde{a}, z) = u'^{-1} \left\{ p_{ij} \max \left\{ \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right], u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \right\} \right\} \quad (156)$$

where u'^{-1} is the inverse function of the marginal utility of consumption.

Side note: One of the interesting things about this equation is that the direct j component on the RHS that only affects the consumption choice is through the price. Can this be exploited? We also know the choice probabilities need to sum to one, so is there a way to map the consumption choice into the choice probabilities? Also, can interpolation be done once how p scales things...

3. The key issue in this method is that we have found $c_{ij}(\tilde{a}, z)$ where the consumption function is associated with some asset level that is not necessarily on the grid. The solution is to (i) use the budget constraint and infer \tilde{a} given that a' was chosen above (that's where we started), z , and $c_{ij}(\tilde{a}, z)$. Now we have a map from \tilde{a} to a' for which one can use interpolation to infer the a' chosen given a where a is on the grid.
- Do steps 2. and 3. for each j variety choice. This then makes the function $g_{ij}(a, z)$ mapping each state and j choice (today) into a', z' states and then from the budget constraint we have an associated consumption function $g_{c,ij}(a, z)$
4. Compute the $E[v(g_{a,ij}(a, z), z')]$. This is performed in the `make_Tv_upwind!` function. It fixes a country j , then works through shocks and asset states today and from the policy function $g_{a,ij}(a, z)$ figures out the asset choice tomorrow. Then the $E[v(g_{a,ij}(a, z), z')]$ is (12) over the different variety choices tomorrow (this is the integration over ϵ) multiplied by the probability of z' occurring (this is the integration over z).
5. Given 4. update the value function using the bellman equation evaluated at the optimal policies:

$$Tv_{ij}(a, z) = u(g_{c,ij}(a, z)) + \beta E[v(g_{a,ij}(a, z), z')] \quad (157)$$

6. Compare old and new policy functions, old and new value functions, and then update accordingly.
