

Heterogeneous Agent Trade

Michael E. Waugh

Federal Reserve Bank of Minneapolis and NBER

June 2022

ABSTRACT

This paper develops a model of heterogeneous agents and international trade. Heterogeneous agents are modeled as in the standard incomplete markets tradition with households facing incomplete insurance against idiosyncratic productivity and taste shocks. Trade in goods follows the Armington tradition but is derived from the “bottom up” with micro-level heterogeneity shaping the aggregate pattern of trade. In the efficient allocation, I recover standard results regarding the gains from trade and gravity. In the decentralized allocation, the pattern of trade is distorted and the benefits from globalization are distributed unequally. I use the model to quantitatively explore two issues: the ability of trade policy to improve outcomes and how trade in financial assets complements trade in goods.

Email: michael.e.waugh@gmail.com. The views expressed herein are those of the author and not necessarily those of the Federal Reserve Bank of Minneapolis or the Federal Reserve System. This project was developed with research support from the National Science Foundation (NSF Award number 1948800).

1. The Heterogeneous Agent Trade Model

This section describes the model and then define the decentralized competitive equilibrium. Trade is in the Armington tradition with each country producing a nationally differentiated variety. Households face the “income fluctuations problem” as in the standard incomplete markets tradition (see, e.g., Chapter 17 of Ljungqvist and Sargent (2012)).

The key twist is that I do not employ modeling techniques with aggregation at household level across national varieties. Instead, I lean into the household heterogeneity and have households make a discrete choice over the varieties they consume in addition to their savings decisions. Aggregate trade flows, trade elasticities, and the gains from trade then defined by the explicit aggregation of household-level decisions to purchase different varieties, their elasticity of demand, and their gains from trade.

1.1. Production and Trade

There are M locations which I call a country. Each country produces a nationally differentiated product as in the Armington tradition. In country i , competitive firms’ production technology to produce variety i is:

$$Q_i = A_i N_i, \tag{1}$$

where A_i is total factor productivity and N_i are the efficiency units of labor supplied by households in country i .¹

In the next several sections, I focus on only one type of barrier to trade: there are iceberg trade costs $d_{ij} > 1$ for a good to go from supplier j to buyer i . In Section ??, I model tariffs and Governments in each country, but for now I focus on these technological barriers to trade.

Profit maximization of the producers in location i results in the wage per efficiency unit reflecting the value of the marginal product of labor

$$w_i = p_i A_i. \tag{2}$$

Given iceberg trade costs, the unit cost for country i to purchase a good from location j is

$$p_{ij} = \frac{d_{ij} w_j}{A_j}. \tag{3}$$

This is the trade and production side of the model. While sparse, it’s worth reminding you

¹Note that lack of physical capital in the model. Households here are saving in via pure exchange of non-state contingent IOUs as in Huggett (1993) rather than in physical capital as in Aiyagari (1994).

(the reader) that with, say, a representative agent and a constant elasticity Armington aggregator much comes out of this model. There is a “gravity equation” relating bilateral trade flows to country characteristics with a constant trade elasticity. And there are two sufficient statistics (the trade elasticity and home trade share) that globally characterize the welfare gains from trade. In the next section, I give up on the representative agent.

1.2. Households

There is a mass of L_i households in each country. Households are immobile across countries. They are infinite lived and have time-separable preferences over consumption of varieties:

$$E_0 \sum_{t=0}^{\infty} \beta^t \tilde{u}(\{c_{ij,t}\}_M), \quad (4)$$

where the notation $\{c_{ij,t}\}_M$ means that the household has preferences over all j varieties supplied by M countries in the world. Here I’m indexing things by ij to denote the variety j that is consumed in location i .

Households’ period utility function is of the random utility class. Specifically, the utility associated with the choice of variety j is

$$\tilde{u}(c_{ij,t}) = u(c_{ij,t}) + \epsilon_{j,t}. \quad (5)$$

where the $\epsilon_{j,t}$ are iid random variables across time, households, and countries. For much of the analysis, I assume that these shocks are distributed Type 1 Extreme Value with dispersion parameter σ_ϵ . For now, all I assume that the utility function over the physical good $c_{ij,t}$ is well behaved. In the analysis below I explore different specifications of the utility function u over the physical commodity and I highlight the rather unique case of log utility.

A household’s efficiency units are stochastic and they evolve according to a Markov chain, i.e. z is a household’s efficiency units and $\mathcal{P}(z, z')$ describes the probability of a household with state z efficiency units transiting to state z' . Again, I assume that \mathcal{P} is well behaved in the necessary ways.

Households can save and borrow in a non-state contingent asset a . One unit of the asset pays out with gross interest rate R_i next period. I discuss this more in depth below, but the determination of R_i is with that which clears the bond market (local or global). A country specific, exogenous debt limit ϕ_i constrains borrowing so:

$$a_{t+1} \geq -\phi_i. \quad (6)$$

All these pieces come together in the household’s budget constraint, conditional on choosing

variety j to consume, and focusing on a stationary setting where prices are constant:

$$p_{ij}c_{ijt} + a_{t+1} \leq R_i a_t + w_i z_t. \quad (7)$$

The value of asset purchases and consumption expenditures must be less than or equal to asset payments, labor earnings.

1.3. The Household Problem

The state variables of a individual household are its asset holdings and efficiency units. As alluded to above, for now I focus on a stationary setting where aggregates are not changing and, thus, I abstract from carrying the notation associated with them around.²

The value function of a household in country i , after the variety shocks are realized, is

$$\tilde{v}_i(a, z) = \max_j \{ v_{ij}(a, z) \} \quad (8)$$

which is the maximum across the value functions associated with the discrete choices of different national varieties. The value function conditional on a choice of variety is

$$v_{ij}(a, z) = \max_{a'} \left\{ u(c_{ij}) + \epsilon_j + \beta \mathbb{E}[v_i(a', z')] \right\} \quad (9)$$

subject to (7) and (6)

where households choose asset holdings and the level of consumption is residually determined through the budget constraint. Associated with the solution to this problem is a policy function $g_{ij}(a, z)$ which solves (9) and maps current states into asset holdings tomorrow a' contingent upon the variety choice.

The continuation value function on the right-hand side of (9) is the expectation over (8) with respect to (i) z' and (ii) the variety taste shocks. One implication of this last point means is that households understand that their may be situations where they really desire, say, a high priced imported good and, hence, save accordingly.

The Type 1 extreme value distribution on the taste shocks give rise to the following choice

²If you *do* want to carry them around, notice that all that households in each country care about are prices (today and in the future). The distributions of households in other countries, per se, don't matter. Thus, the relevant aggregate states in country i are $[\{w_i\}_M, R_i]$ which is the collection wage per efficiency units and the interest rate.

probabilities for each differentiated good:

$$\pi_{ij}(a, z) = \exp\left(\frac{v_{ij}(a, z)}{\sigma_\epsilon}\right) \Bigg/ \sum_{j'} \exp\left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon}\right), \quad (10)$$

which is the probability that a household with assets a and efficiency units z chooses country variety j . And then the expectation of (8) with respect to the taste shocks takes the familiar log-sum form

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \sum_{j'} \exp\left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon}\right) \right\}. \quad (11)$$

Associated with this problem in (9) is the a Euler Equation for each variety choice j :

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \beta R_i \mathbb{E}_{z'} \left[\sum_{j'} \pi_{ij'}(a', z') \frac{u'(c_{ij'}(a', z'))}{p_{ij'}} \right] \quad (12)$$

that holds for non-borrowing-constrained households. This has a very natural interpretation: a household equates marginal utility of consumption today with expected discounted marginal utility of consumption tomorrow adjusted by the return on delaying consumption. The interesting feature here is that the expected value of the marginal utility of consumption reflects the uncertainty over one's preference over different varieties tomorrow via the choice probabilities and note that households has some control over these probabilities as the asset choice today influence the choice probabilities tomorrow.

Before moving on to aggregation, I'm going to make one useful observation that helps with some of the analysis. Stare at (10) and (11) long enough, one can arrive a kind of dynamic, sufficient statistic representation of $v_i(a, z)$ where it is purely summarized by home choices. Appendix 5 works through the individual steps, but (11) can be summarized as

$$v_i(a, z) = -\sigma_\epsilon \log \pi_{ii}(a, z) + u(c_{ii}(a, z)) + \beta \mathbb{E}_{z'} v_i(a', z'). \quad (13)$$

Here the ex-ante value function (prior to the realization of the preference shocks) is expressed as a sum of the log home choice probability, utility over physical consumption of the home good, and recursively the expected value function tomorrow. What's going on here is that the home choice probability π_{ii} completely summarizes the expected value of the taste shocks, their benefits, and how households respond to them in the future.³

³Home choice probabilities are not necessarily the same as home trade shares, but this is closely related to Equation (15), Footnote 42 of Eaton and Kortum (2002) and I'm heading towards situations where this result plus restrictions on u give rise to the result in Arkolakis et al. (2012).

Equation (13) together with (12) also provides more insight about the how the savings motives of households interact with the variety choice. Focusing on a household consuming the home good (and note that the left-hand-side below could be for any variety choice), I can rewrite the Euler Equation in (12) as:

$$\frac{u'(c_{ii}(a, z))}{p_{ii}} = \beta \mathbb{E} \left\{ -\sigma_\epsilon \frac{\partial \pi_{ii}(a', z') / \pi_{ii}(a', z')}{\partial a'} + \frac{u'(c_{ii}(a', z')) R}{p_{ii}} \right\}, \quad (14)$$

which says that an unconstrained household should be indifferent between the marginal utility of consumption forgone to hold some more assets and two components: (i) the benefit from how a change in assets changes in their variety choice in the future and this is summarized by the change in the home choice probability and (ii) the direct benefit of the returns on the assets evaluated at the marginal utility of consumption.

1.4. Aggregation

In this section, I explicitly aggregate household behavior. At the core of aggregation is a probability distribution $\lambda_i(a, z)$ which describes the measure of households across the individual states. This distribution evolves according to

$$\lambda_i(a', z') = \sum_j \int_z \int_{a: a' = g_{ij}(a, z)} \pi_{ij}(a, z) \mathcal{P}(z, z') \lambda_i(a, z). \quad (15)$$

where the inner most term describes the mass of households choosing variety j , multiplied by the probability that z transits to z' , multiplied by the existing measure of households with states a and z . This is integrated with respect to those actually choosing asset holdings a' , over all z 's, and then summed over the different variety choices.

Given this distribution, everything else follows. Aggregate efficiency units are

$$N_i = L_i \int_z \int_a z \lambda_i(a, z). \quad (16)$$

And then the aggregate quantity of asset holdings integrates across the asset choices of individual households

$$A'_i = L_i \sum_j \int_z \int_a g_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z). \quad (17)$$

From here, I reconstruct national income and product identities. Starting from the production

side, the value of aggregate production must equal aggregate payments to labor so

$$p_i Y_i = p_i A_i N_i = L_i \int_z \int_a w_i z \lambda_i(a, z) \quad (18)$$

where the last term sums over wage payments for each household type. Then by summing over individual consumers' budget constraint and substituting in (18), we arrive at the aggregated budget constraint:

$$p_i Y_i = \widetilde{P_i C_i} + \left[-R_i A_i + A'_i \right], \quad (19)$$

where national income equals the value of aggregate consumption $\widetilde{P_i C_i}$ and the country's net factor payments plus its net asset position. The value of aggregate consumption is

$$\widetilde{P_i C_i} = L_i \sum_j \int_z \int_a p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z) \quad (20)$$

where one can see a bug and a feature of this model. Here there is an "index number problem" in the sense that there is not an ideal price index for which one can decompose aggregate values into a price and quantity component. This is in contrast to, e.g., a model where households consume a CES bundle of goods.

To complete the national income accounting, I construct aggregate imports as

$$M_{ij} = L_i \int_z \int_a p_{ij} c_{ij}(a, z) \pi_{ij}(a, z) \lambda_i(a, z). \quad (21)$$

Then aggregate exports from country i to country j are constructed in a similar manner.

$$X_{ji} = L_j \int_z \int_a p_{ji} c_{ji}(a, z) \pi_{ji}(a, z) \lambda_i(a, z) \quad (22)$$

Then the standard national income accounting identity arises

$$p_i Y_i = \widetilde{P_i C_i} + \left[\sum_{j \neq i} X_{ji} - \sum_{j \neq i} M_{ij} \right] \quad (23)$$

where national production or GDP equals consumption plus exports minus imports. A comparison of (19) and (23) then makes clear that the trade imbalance is connected with a country's net factor payments and net asset position.

This observation has implications beyond accounting. Inspection of the individual elements in (17), (21) and the households' budget constraint reveal that household's asset positions are

intertwined with trade flows through both the intensive (how much to consume and, hence, save) and the extensive margins (which variety to consume). Thus, a feature of this model is that the trade side is interlinked way with the financial side of the economy in a non-trivial.

1.5. The Decentralized Equilibrium

In this section, I discuss the market clearing conditions that an equilibrium must respect and then define the Decentralized Equilibrium of this economy.

The Goods Market. Goods market clearing equates the value of production of commodity i with global demand for country i 's commodity:

$$p_i Y_i = \sum_j X_{ji}, \quad (24)$$

where the left hand side is production and the right hand side is world demand for the commodity (via exports) from (22).

The Bond Market. The second market clearing condition is in the bond market. For most of the paper, I'm thinking about the case of "financial autarky" in which there is a local bond market that facilitates within country asset trade, but not across countries. In this case, there is an interest rate R_i for each country and the associated market clearing condition is

$$A'_i = 0, \quad \forall i \quad (25)$$

which says that net asset demand within each country i must be zero. As is common in the trade literature, this condition implies that trade is balanced—just stare at (19) and (23). Yet, even with balanced trade, there is still within country trade of financial assets. Some households are savers, others are borrowers and the interest rate is that which the net asset position is zero.

Below I formally define the Decentralized Stationary Equilibrium where private market participants taking prices as given solve their problems, the distribution of households is stationary, and prices are consistent with market clearing.

The Decentralized Stationary Equilibrium. A Decentralized Stationary Equilibrium are asset policy functions and commodity choice probabilities $\{g_{ij}(a, z), \pi_{ij}(a, z)\}_i$, probability distributions $\{\lambda_i(a, z)\}_i$ and positive real numbers $\{w_i, p_{ij}, R_i\}_{i,j}$ such that

- i Prices (w_i, p_{ij}) satisfy (2) and (3);
- ii The policy functions and choice probabilities solve the household's optimization problem in (8) and (9);
- iv The probability distribution $\lambda_i(a, z)$ induced by the policy functions, choice probabilities,

and primitives satisfies (15) and is stationary;

v Goods market clears:

$$p_i Y_i - \sum_j^M X_{ji} = 0, \quad \forall i \quad (26)$$

v Bond market clears with

$$A'_i = 0, \quad \forall i \quad (27)$$

1.6. Outline of the rest of paper

This model above has households making individual choices over national varieties, savings, all while facing productivity and taste shocks. Explicit aggregation of household behavior determines the pattern of trade and this is linked with trade in financial assets. The remaining sections of the paper work through the following questions:

1. **What does the efficient, centralized allocation look like. And what are the gains from trade?** The model features an inefficiency arising from market incompleteness. Households would like insurance against future shocks to income, but only have a partial ability to provide themselves this insurance. Endowing a central planner with the ability to overcome this friction and studying the resulting allocation helps illustrate the behavior of model in the decentralized allocation.
2. **What are the gains from trade in decentralized allocation?** Here, surprisingly, a lot can be said. I connect the results with those from the Centralized Allocation and benchmarks in the literature such as Arkolakis et al. (2012). I also workout a knife edge case when utility is log over consumption and how it delivers complete severation from the heterogeneous agents and trade.
3. The final section focuses on quantitative analysis.

2. The Centralized Equilibrium

This section describes the Centralized (Efficient) Equilibrium. The starting point is taking a stand on a Social Welfare function. I focus on a utilitarian social welfare function so Pareto weights across households, within a country, are the same and then across countries they are

proportional to the number of households residing in those countries

$$W = \sum_{t=0}^{\infty} \sum_i \int_z \beta^t v_i(z, t) L_i \lambda_i(z, t),$$

and here v_i a households utility in country i . Now, I'm going unpack the benefits from physical commodity and the preference shock in the following way:

$$W = \sum_{t=0}^{\infty} \sum_i \sum_j \int_z \beta^t \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (28)$$

so the inner term is period utility given the associated consumption allocation c_{ij} and then the expected value of the preference shock conditional on the choice probability $\pi_{ij}(z, t)$. This inner term is then weighted by the number of households that receive that utility, i.e. the choice probability times the mass of households with shock z at date t . The sum across j adds up all households in country i . Then the sum across i reflects that this is global welfare.

The Planner chooses consumption allocations $c_{ij}(z, t)$ and choice probabilities $\pi_{ij}(z, t)$ for all i, j pairs, z states, and dates t to maximizes (28). This maximization problem is subject to two constraints. The first is the resource constraint:

$$Y_{it} \geq \sum_j \int_z d_{ji} c_{ji}(z, t) \pi_{ji}(z, t) L_j \lambda_j(z, t), \quad (29)$$

which says that production of variety i must be greater than or equal to world consumption of variety i inclusive of trade costs d_{ji} . The second constraint is that the choice probabilities are probabilities and sum to one:

$$1 = \sum_j \pi_{ij}(z, t). \quad (30)$$

Given these constraints I define the **Centralized Planner's Problem** as the following:

$$\max_{c_{i,j}(z,t), \pi_{i,j}(z,t)} \sum_{t=0}^{\infty} \sum_i \sum_j \beta^t \int_z \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (31)$$

$$\text{subject to (29), (30) and an initial condition } \lambda_i(z, 0). \quad (32)$$

In Appendix D, I derive the solution to this problem. Proposition 1 describes the allocation that maximizes social welfare and, hence, is what I will call the efficient allocation.

Proposition 1 (The Efficient Allocation) *The allocation that satisfies the Centralized Planning Problem in (31) is:*

1. A consumption allocation satisfying:

$$u'(c_{ij}(z, t)) = \chi_j(t)d_{ij} \quad (33)$$

where $\chi_j(t)$ is the shadow price of variety j .

2. The choice probabilities are

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t))c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t))c_{ij'}(t)}{\sigma_\epsilon} \right) \quad (34)$$

and are independent of z because of (33).

Proposition 1 has some neat features. First, the consumption allocation takes on the natural feature that the marginal utility of consumption equals its shadow price adjusted by the trade friction. Here the shadow price is the resource constraint's multiplier $\chi_j(t)$. Because the shadow price only reflects the scarcity of the commodity, the marginal utility of consumption (and consumption) then does not depend upon z . So if a household is productive or unproductive at date, t , the Planner equates the marginal utility of consumption across these states (within variety). This is the sense in which the planner is providing insurance across households.

Another implication is that (33) means that the marginal utility of consumption is *not* equated across households as one would typically expect where all households are consuming the same good. What (33) does imply is that the ratio of marginal utility of consumption adjusted by relative shadow prices should be equal as in Backus and Smith (1993).

The second part of Proposition 1 prescribes the mass of households that consume variety j . Per the distributional assumption on the taste shocks, the choice probabilities in (34) take the form of ratio's of exp relative to sum of exp functions with the dispersion parameter σ_ϵ showing up in the natural way.

The interpretation of the terms within the exp function take on a very intuitive form: it's the net social benefit of assigning a household to consume that variety. Net is here because it's the difference between the utility received $u(c_{ij}(t))$ minus the social cost $u'(c_{ij}(t))c_{ij}(t)$. Why is that the social cost? From (33), the marginal utility of consumption exactly reflects the scarcity of providing $c_{ij}(t)$. Thus, the interpretation is that variety assignment is based upon the social benefit $u(c_{ij}(t))$ net of providing that benefit, in total, so $u'(c_{ij}(t))c_{ij}(t)$.

Given Proposition 1, I can compute the welfare gains from a change in trade costs. I do this by focusing on stationary allocations, so t 's are not relevant. And then study how welfare changes

across the two stationary allocations. Here it is of no consequence as there is no moving aggregate state variable in the allocation, so the jump across stationary equilibrium is instantaneous.

Appendix D works out the details, Proposition 2 describes the result.

Proposition 2 (The Welfare Gains from Trade in the Efficient Allocation) *The welfare gains from a reduction in trade costs are*

$$\frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{1}{1 - \beta} \times u'(c_{ij})c_{ij}\pi_{ij}L_i$$

which is the discounted, direct effect from relaxing the resource constraint in (29). The direct effect is equivalent to

$$u'(c_{ij})c_{ij}\pi_{ij} = -\sigma_\epsilon \frac{\partial \pi_{ii}/\pi_{ii}}{\partial d_{ij}/d_{ij}}, \quad (35)$$

the elasticity of the home choice probability multiplied by the dispersion parameter σ_ϵ .

Proposition 2 says that the welfare gains equal the amount being eaten $c_{ij}\pi_{ij}(t)L_i$ times the social valuation of the commodity which is the marginal utility of consumption. This gain is then discounted for the infinite future, hence the $1/(1 - \beta)$ term. What this says that the gains from trade come from the direct effect from relaxing the resource constraint. That is, that there are less resources destroyed by trade costs and this directly allows for more consumption of commodity j by those consuming that commodity in country i .

This result is reminiscent of Atkeson and Burstein (2010) who make a similar claim in the context of firm heterogeneity. More specifically, they argue that the only first order effect lower trade costs have on welfare in a rich model of firm heterogeneity is the direct consumption effect and that indirect effects are second order. This is similar, but with household heterogeneity, by saying that in the efficient allocation the welfare gains are these direct consumption benefits.

The next part of 2 connects with Arkolakis et al. (2012). It describes the sufficient statistic for understanding the gains from trade. It says that the direct effect can be summarized by the elasticity of the home choice probability multiplied by a term reflecting the dispersion in taste shocks. So it picks up natural Armington-CES logic so that if σ_ϵ is small, then national varieties are “as if they are near substitutes” and hence changes in trade lead to small benefits relative to a scenario with large σ_ϵ (holding fixed that trade changes by the same amount).

3. Trade Elasticities and Gains from Trade

This section focuses on the decentralized equilibrium and I provide a description of how micro-level decisions shape the aggregate trade elasticity and then the gains from trade and the

sources of those gains.

3.1. Trade Elasticities

My definition of the trade elasticity is the partial equilibrium response of imports from j relative to domestic consumption due to a permanent change in trade costs between steady states. By partial equilibrium, I mean that wages and interest rates are fixed at their initial equilibrium values. By permanent, I work this out under the heuristic of a “steady-state to steady-state comparison” where I factor in how the stationary distribution changes due to changes in behavior.⁴ This definition is consistent with the broad terminology used in the trade literature, e.g. Arkolakis et al. (2012) and Simonovska and Waugh (2014).

Working off of the definition of aggregate imports in (21), Proposition 3 defines the aggregate trade elasticity.

Proposition 3 (The Heterogenous Agent Trade Elasticity) *The trade elasticity between country i and country j is:*

$$\theta_{ij} = \sum_{a,z} \left\{ \theta_{ij}(a,z)^I + \theta_{ij}(a,z)^E + \theta_{ij}(a,z)^D \right\} \omega_{ij}(a,z) - \left\{ \theta_{ii}(a,z)^I + \theta_{ii}(a,z)^E + \theta_{ii}(a,z)^D \right\} \omega_{ii}(a,z) \quad (36)$$

which is the difference between ij and ii expenditure-weighted micro-level elasticities. The micro-level elasticities for households with states a, z are decomposed into an intensive, extensive, and distributional elasticity

$$\theta_{ij}(a,z)^I = \frac{\partial p_{ij} c_{ij}(a,z) / p_{ij} c_{ij}(a,z)}{\partial d_{ij} / d_{ij}}, \quad \theta_{ij}(a,z)^E = \frac{\partial \pi_{ij}(a,z) / \pi_{ij}(a,z)}{\partial d_{ij} / d_{ij}}, \quad \theta_{ij}(a,z)^D = \frac{\partial \lambda_i(a,z) / \lambda_i(a,z)}{\partial d_{ij} / d_{ij}},$$

and the expenditure weights are defined as

$$\omega_{ij}(a,z) = \frac{p_{ij} c_{ij}(a,z) \pi_{ij}(a,z) \lambda_i(a,z)}{M_{ij}}.$$

Proposition 3 essentially says the following: The aggregate trade elasticity is an expenditure weighted average of micro-level trade elasticities. And these micro-level trade elasticities are decomposed into three components. First, there is an intensive margin trade elasticity $\theta_{ij}(a,z)^I$ reflecting the change in spending by a household on variety from j as trade costs change. Second, there is the extensive margin trade elasticity $\theta(a,z)^E_{ij}$ reflecting how households substitute across varieties as trade costs change.

The final term the distribution elasticity $\theta(a,z)^D_{ij}$ which reflects how mass of agents change across states a, z . This last elasticity may seem a bit odd in a partial equilibrium elasticity. But

⁴This is heuristic in the sense that because aggregate states depend upon the distribution of households, then the model will feature non-trivial transition paths across steady states and generically trade elasticities that vary along the path.

I include it here because the flip side of changes in the intensive and extensive margin is that household saving behavior changes (even at fixed wages and interest rates) as the change in trade costs provides more resources and substitution across products. It's in this sense that it's a relevant margin to keep track of.

Proposition 3 is derived only off the aggregation of imports at the micro level—no market clearing, functional forms, etc. However, by using the households budget constraint and the Type 1 extreme value assumption I can say more about these elasticities and how the household's consumption-savings problem influences them.

The Intensive Margin Trade Elasticity. By using the households budget constraint in (7) the intensive margin elasticity becomes:

$$\underbrace{\frac{\partial p_{ij} c_{ij}(a, z) / p_{ij} c_{ij}(a, z)}{\partial d_{ij} / d_{ij}}}_{\theta_{ij}(a, z)^I} = - \frac{\partial g_{ij}(a, z)}{\partial p_{ij} / p_{ij}} \frac{\partial p_{ij} / p_{ij}}{\partial d_{ij} / d_{ij}} \times \frac{1}{p_{ij} c_{ij}(a, z)}, \quad (37)$$

$$= - \frac{\partial g_{ij}(a, z)}{\partial p_{ij} / p_{ij}} \frac{1}{p_{ij} c_{ij}(a, z)}, \quad (38)$$

where $g_{ij}(a, z)$ is the policy function mapping states into asset holdings next period a' . And the last line follows from perfect pass-through of changes in trade costs to prices, $\frac{\partial p_{ij} / p_{ij}}{\partial d_{ij} / d_{ij}} = 1$.

Equation (38) says that the intensive margin elasticity is related to how a household adjusts its wealth relative to expenditure, given change in the price p_{ij} . To be concrete, the way this works is that a reduction in trade costs lowers prices and relaxes the household's budget constraint—conditional on choice j . And then the intensive margin elasticity depends on how the new resources are divided between assets and consumption.

The Extensive Margin Trade Elasticity. With the Type 1 extreme value distributional assumption, I can connect how the choice probabilities change and a household's problem. As a first step, define the denominator of the choice probability in (10) as:

$$\Phi_i(a, z) = \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right). \quad (39)$$

The elasticity of the choice probability with respect to a change in trade costs is

$$\underbrace{\frac{\partial \pi_{ij}(a, z) / \pi_{ij}(a, z)}{\partial d_{ij} / d_{ij}}}_{\theta_{ij}(a, z)^E} = - \frac{\partial \Phi_i(a, z) / \Phi_i(a, z)}{\partial d_{ij} / d_{ij}} + \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij} / d_{ij}}. \quad (40)$$

The first term reflects the fact that the change choice j depends upon a comparison relative to

the overall change in the value of options across variety. This is very much similar to how CES models behave except that this term is state a, z specific.

The second term reflects how the choice specific value function changes with trade costs multiplied by the taste shock parameter. In other words, how elastic or inelastic the extensive margin is depends on how much more valuable choice j becomes. And if goods are like “near substitutes” with a small σ_ϵ , then the extensive margin is more elastic.

Here is a little more insight about what shapes the choice specific value function. This can be written as the following:

$$\begin{aligned} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = & -u'(c_{ij}(a, z))c_{ij}(a, z) \\ & + \underbrace{\left\{ \frac{-u'(c_{ij}(a, z))}{p_{ij}} + \beta \mathbb{E} \left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + \frac{u'(c_{ii}(a', z'))}{p_{ii}} R_i \right] \right\}}_{\text{Euler equation in (14)}} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \\ & + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial p_{ij}/p_{ij}} \Bigg\}. \end{aligned} \quad (41)$$

I’m going to focus on the first and second terms; the final term in (41) says that the extensive margin elasticity depends upon how things change in the future idiosyncratically as z evolves and through the behavioral response of assets.

The first term in (41) is the private, direct gain from a change in trade costs. In a sense, this term is mimicking the $u'(c)c$ term in the efficient allocation of Proposition 1, but here private returns are not aligned with social returns due to market incompleteness.

One more step shows how the first term in (41) varies with the wealth of a household. Differentiate $u'(c_{ij}(a, z))c_{ij}(a, z)$ with respect to assets. The thought experiment here is if a household was a bit wealthier what would the effect be on the extensive margin elasticity:

$$\frac{\partial(u'(c_{ij}(a, z))c_{ij}(a, z))}{\partial a} = u'(c_{ij}(a, z)) \times \text{MPC}_{ij}(a, z) \times \left[-\rho_{ij}(a, z) + 1 \right], \quad (42)$$

where $\text{MPC}_{ij}(a, z)$ is the household’s marginal propensity to consume and $\rho_{ij}(a, z)$ is the Arrow-Pratt measure of relative risk aversion.

Putting (42) in the context of Constant Relative Risk Aversion (CRRA) preferences makes things clear. If relative risk aversion is greater than one, this implies that poor, high marginal utility households who are also likely high MPC households are *more elastic relative* to rich households

on the extensive margin—holding everything else fixed.⁵ This is the sense in which wealthy or poor households will have systematically different extensive margin elasticities and, like the discussion around the intensive margin elasticity, the households consumption-savings motives play a role.

The second term reflects the impact of the borrowing constraint. What this means is if a household is not borrowing constrained, it's Euler equation holds and then the second term is zero. Borrowing constrained households will not be on their Euler equation and this *may* be a force to make households more elastic. But because the change in the asset policy function multiplies the outside term, it only matters for those whom the price change allows them to go from constrained to unconstrained.

⁵In the log preference case (and I work through this case more in depth below), this term becomes zero and the first term in (41) is constant and not varying with wealth.

Appendix

A. The Generalized Trade Elasticity

My definition of the trade elasticity is the partial equilibrium response of imports from j relative to domestic consumption due to a permanent change in trade costs between steady states. By partial equilibrium, I mean that wages and interest rates are fixed at their initial equilibrium values. By permanent, I work this out under the heuristic of a “steady-state to steady-state comparison” where I factor in how the stationary distribution changes due to changes in behavior. This definition is consistent with the broad terminology used in the trade literature, e.g. Arkolakis et al. (2012) and Simonovska and Waugh (2014). Consistent with this discussion and the notation below, I compute the partial derivatives (not total) of objects with respect to trade costs.

Mathematically, the trade elasticity equals the difference between the elasticities for how trade between i and j change minus how home trade changes:

$$\frac{\partial(M_{ij}/M_{ii})}{\partial d_{ij}} \times \frac{d_{ij}}{(M_{ij}/M_{ii})} = \frac{\partial(M_{ij}/M_{ij})}{\partial d_{ij}/d_{ij}} - \frac{\partial(M_{ij}/M_{ii})}{\partial d_{ij}/d_{ij}}. \quad (43)$$

The change in imports between i and j with respect to a change in trade costs is:

$$\frac{\partial M_{ij}}{\partial d_{ij}} = \sum_{a,z} \left\{ \frac{\partial p_{ij}c_{ij}(a,z)}{\partial d_{ij}} \pi_{ij}(a,z) \lambda_i(a,z) + \frac{\partial \pi_{ij}(a,z)}{\partial d_{ij}} p_{ij}c_{ij}(a,z) \lambda_i(a,z) + \frac{\partial \lambda_i(a,z)}{\partial d_{ij}} p_{ij}c_{ij}(a,z) \pi_{ij}(a,z) \right\}. \quad (44)$$

Divide the stuff on the inside of the brackets by household level imports $p_{ij}c_{ij}(a,z)\pi_{ij}(a,z)\lambda_i(a,z)$ and multiply on the outside giving,

$$\frac{\partial M_{ij}}{\partial d_{ij}} = \sum_{a,z} \left\{ \frac{\partial p_{ij}c_{ij}(a,z)/p_{ij}c_{ij}(a,z)}{\partial d_{ij}} + \frac{\partial \pi_{ij}(a,z)/\pi_{ij}(a,z)}{\partial d_{ij}} + \frac{\partial \lambda_i(a,z)/\lambda_i(a,z)}{\partial d_{ij}} \right\} p_{ij}c_{ij}(a,z)\pi_{ij}(a,z)\lambda_i(a,z). \quad (45)$$

Define the following weight which is the share of goods that those with states a, z account for in total expenditures from j as

$$\omega_{ij}(a,z) = \frac{p_{ij}c_{ij}(a,z)\pi_{ij}(a,z)\lambda_i(a,z)}{M_{ij}}. \quad (46)$$

where the sum of $\omega_{ij}(a,z)$ equals total imports M_{ij} . This gives a nice expression for the import

elasticity

$$\frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}} = \sum_{a,z} \left\{ \underbrace{\frac{\partial p_{ij}c_{ij}(a,z)/p_{ij}c_{ij}(a,z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^I} + \underbrace{\frac{\partial \pi_{ij}(a,z)/\pi_{ij}(a,z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^E} + \underbrace{\frac{\partial \lambda_i(a,z)/\lambda_i(a,z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a,z)^D} \right\} \omega_{ij}(a,z) \quad (47)$$

or more succinctly as

$$\frac{\partial M_{ij}/M_{ij}}{\partial d_{ij}/d_{ij}} = \sum_{a,z} \left\{ \theta_{ij}(a,z)^I + \theta_{ij}(a,z)^E + \theta_{ij}(a,z)^D \right\} \omega_{ij}(a,z) \quad (48)$$

where the elasticity of aggregate imports into i from j is a weighted average of three different micro-level elasticities. The micro-level elasticities are:

- (i) An intensive margin trade elasticity $\theta_{ij}(a,z)^I$ which reflects the change in spending by a household on variety from j as trade costs decline.
- (ii) The next term is the extensive margin trade elasticity $\theta_{ij}(a,z)^E$ which reflects how households substitute across varieties as trade costs decline. As I show below in Section ??, this takes the place as the standard trade elasticity in, e.g., Eaton and Kortum (2002).
- (iii) The distribution elasticity $\theta_{ij}(a,z)^D$ so how the mass of agents change across household states a, z . This last elasticity may seem a bit odd as being present in a partial equilibrium elasticity. But I include it here because the flip side of changes in the intensive and extensive margin is that household saving behavior (even at fixed wages and interest rates) generally will change with the commodity choice. It's in this sense that it's a relevant margin to keep track of.

Given the expression in (43), Proposition 4 follows:

Proposition 4 (The Generalized Trade Elasticity) *The trade elasticity between country i and country j is:*

$$\theta_{ij} = \sum_{a,z} \left\{ \theta_{ij}(a,z)^I + \theta_{ij}(a,z)^E + \theta_{ij}(a,z)^D \right\} \omega_{ij}(a,z) - \left\{ \theta_{ii}(a,z)^I + \theta_{ii}(a,z)^E + \theta_{ii}(a,z)^D \right\} \omega_{ii}(a,z) \quad (49)$$

which is the difference in expenditure weighted micro-level elasticities. The micro-level elasticities for households with states a, z are decomposed into an intensive, extensive, and distributional elasticity

$$\theta_{ij}(a,z)^I = \frac{\partial p_{ij}c_{ij}(a,z)/p_{ij}c_{ij}(a,z)}{\partial d_{ij}/d_{ij}}, \quad \theta_{ij}(a,z)^E = \frac{\partial \pi_{ij}(a,z)/\pi_{ij}(a,z)}{\partial d_{ij}/d_{ij}}, \quad \theta_{ij}(a,z)^D = \frac{\partial \lambda_i(a,z)/\lambda_i(a,z)}{\partial d_{ij}/d_{ij}}$$

and the expenditure weights are defined as

$$\omega_{ij}(a, z) = \frac{p_{ij}c_{ij}(a, z)\pi_{ij}(a, z)\lambda_i(a, z)}{M_{ij}}$$

An interesting feature of Proposition 4 is that it's derived only off the aggregation of imports at the micro level—no market clearing, functional forms, etc. However, by using the households budget constraint and the Type 1 extreme value distributional assumption more can be said about these elasticities and illustrate how the household's consumption-savings problem matters.

By using the households budget constraint one can express the intensive margin elasticity as

$$\underbrace{\frac{\partial p_{ij}c_{ij}(a, z)/p_{ij}c_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a, z)^I} = -\frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} \times \frac{1}{p_{ij}c_{ij}(a, z)}, \quad (50)$$

$$= -\frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \times \frac{1}{p_{ij}c_{ij}(a, z)}, \quad (51)$$

where recall that $g_{ij}(a, z)$ is the policy function mapping states into asset holdings next period a' and the last line follows from $\frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} = 1$. What this means is that the intensive margin elasticity is about a households consumption-savings behavior, i.e., how a household adjusts assets given a change in the price p_{ij} .

The Type 1 extreme value assumption allows for a characterization of how the choice probabilities change. As a first step, define the denominator of the choice probability as:

$$\Phi_i(a, z) = \sum_{j'} \exp\left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon}\right). \quad (52)$$

The elasticity of the choice probability with respect to a change in trade costs is

$$\underbrace{\frac{\partial \pi_{ij}(a, z)/\pi_{ij}(a, z)}{\partial d_{ij}/d_{ij}}}_{\theta_{ij}(a, z)^E} = \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i(a, z)/\Phi_i(a, z)}{\partial d_{ij}/d_{ij}}. \quad (53)$$

Now interestingly, I can say more about the value function part

$$\frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = -u'(c_{ij}(a, z))c_{ij}(a, z) + \left[-\frac{u'(c_{ij}(a, z))}{p_{ij}} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \right] + \beta \mathbb{E} \left\{ \frac{\partial v}{\partial a'} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} \right. \quad (54)$$

$$\left. + \frac{\partial v(\overline{g_{ij}(a, z)}, z')}{\partial p_{ij}/p_{ij}} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} \right\} \quad (55)$$

which can then be further expressed using the Euler equation below as

$$\frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} = -u'(c_{ij}(a, z))c_{ij}(a, z) \quad (56)$$

$$+ \left\{ -\frac{u'(c_{ij}(a, z))}{p_{ij}} + \beta \mathbb{E} \left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z'))R \right] \right\} \frac{\partial g_{ij}(a, z)}{\partial p_{ij}/p_{ij}} \quad (57)$$

$$+ \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial p_{ij}/p_{ij}} \left\} \quad (58)$$

I can then connect the first term with things like the relative risk aversion and the marginal propensity to consume. The thought experiment here is if a household was a bit wealthier what would the effect be on the $u'(c_{ij}(a, z))c_{ij}(a, z)$ and hence how one component of the extensive margin elasticity changes:

$$\frac{\partial(u'(c_{ij}(a, z))c_{ij}(a, z))}{\partial a} = u''(c_{ij}(a, z)) \frac{\partial c_{ij}}{\partial a} c_{ij}(a, z) + u'(c_{ij}(a, z)) \frac{\partial c_{ij}}{\partial a} \quad (59)$$

$$= \frac{\partial c_{ij}}{\partial a} \left[u''(c_{ij}(a, z))c_{ij}(a, z) + u'(c_{ij}(a, z)) \right] \quad (60)$$

$$= u'(c_{ij}(a, z)) \times \mathbf{MPC}_{ij}(a, z) \times \left[-\rho_{ij}(a, z) + 1 \right]. \quad (61)$$

And just to emphasize how this works, it's a derivative of $u'(c_{ij}(a, z))c_{ij}(a, z)$. So as assets go up, with $\rho > 1$ this implies that $u'(c_{ij}(a, z))c_{ij}(a, z)$ goes down! And this is a force for things to be less elastic for rich guys. As assets go down, this implies that $u'(c_{ij}(a, z))c_{ij}(a, z)$ goes up, and this is a force for poor guys to be more elastic.

The Distribution Trade Elasticity. I can connect the intensive and extensive margin trade elas-

ties with how the distribution changes in the following way. First, notice that the mass of households $\lambda_i(a, z)$ depends if a function of the asset policy function $g_{ij}(a, z)$ and the choice probability $\pi_{ij}(a, z)$. Represent this function as

$$\lambda_i(a, z) = f_\lambda(\pi_{ij}(a, z), g_{ij}(a, z)), \quad (62)$$

Then we can express how the distribution changes

$$\frac{\partial \lambda_i(a, z)/\lambda_i(a, z)}{\partial d_{ij}/d_{ij}} = \frac{\partial f_{\lambda,1}/f_\lambda}{\partial d_{ij}/d_{ij}} \frac{\partial \pi_{ij}(a, z)}{\partial d_{ij}} + \frac{\partial f_{\lambda,2}/f_\lambda}{\partial d_{ij}/d_{ij}} \frac{\partial g_{ij}(a, z)}{\partial d_{ij}} \quad (63)$$

which emphasizes the point that how the distribution changes is fundamentally interlinked to the behavioral responses of households through how they substitute across products and how they substitute across time.

B. The Welfare Gains from Trade

This section derives the gains from a permanent change in trade costs, across steady states. Like the discussion above, the idea here is that I'm thinking a situation where the change is small and there is an immediate jump to the new steady state. Unlike the trade elasticity, I'm going to take total derivatives that will encompass general equilibrium changes in wages and interest rates.

The analysis proceeds in several steps.

First, I'm going to focus on country i and study a change in trade costs d_{ij} . To simplify the algebra, I'm going to choose w_i to be the numeraire. Then I'm going to normalize $A_i = 1$. What this implies is that $p_{ii} = \frac{w_i}{A_i}$ equals one and it's derivative with respect to things is zero.

Second, To compute how social welfare changes, I focus on a utilitarian social welfare function (Pareto weights across households, within a country, are the same):

$$W_i = \sum_{a,z} v_i(a, z) \lambda_i(a, z) \quad (64)$$

Then the total change in total welfare is

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \sum_{a,z} \left\{ \frac{dv_i(a, z)}{dd_{ij}/d_{ij}} + v_i(a, z) \frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}} \right\} \lambda_i(a, z). \quad (65)$$

What illustrates is that the gains from trade come through two forces. The first component reflects changes in household-level welfare. So conditional on a distribution of households across states, are households better or worse off. The second component is about reallocation,

i.e., if—at the old v 's—does the distribution change so that social welfare gets better or worse. The change in social welfare is then the weighted average of these two forces with the weights being those at the initial distribution.

How does household-level welfare change? With the Type 1 extreme value distribution some progress can be made in several steps. First, notice that I can express everything relative to the home country i . Recall that the value function (with the expectation taken over the different preference shocks) is

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) \right\}, \quad (66)$$

and then I'm going to make the observation that I can substitute out the sum part (66 with the exp of the home value function relative to the micro-level “home choice” so

$$\pi_{ii}(a, z) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right), \quad (67)$$

$$\pi_{ii}(a, z) \times \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right), \quad (68)$$

$$\sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) = \exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right) / \pi_{ii}(a, z). \quad (69)$$

Then substituting (69) into the value function in (66) gives:

$$v_i(a, z) = \sigma_\epsilon \log \left\{ \frac{\exp \left(\frac{v_{ii}(a, z)}{\sigma_\epsilon} \right)}{\pi_{ii}(a, z)} \right\} \quad (70)$$

and recall that the home choice value function is

$$v_{ii}(a, z) = u(c_{ii}(a, z)) + \beta \mathbb{E} v_i(g_{ii}(a, z), z) \quad (71)$$

where the expectation operator is over the z s and the v_i is the same value function as in (66) so the taste shocks are integrated out. Taking logs and exp's of (70) allows for the v_i value function to be represented as

$$v_i(a, z) = -\sigma_\epsilon \log \pi_{ii}(a, z) + u(c_{ii}(a, z)) + \beta \mathbb{E} v_i(g_{ii}(a, z), z). \quad (72)$$

The key innovation here is that now everything is written with respect to the home choice. Where are the taste shocks? What is going on is that the home choice π_{ii} summarizes the expected value of those shocks and their benefits. No need to explicitly carry around the v_{ij} s. This is essentially the dynamic analog to Equation (15), Footnote 42 of Eaton and Kortum (2002) and Arkolakis et al. (2012) and I explicitly show this in the example section below.

Now the strategy is to totally differentiate (72) with respect to trade costs and use the recursive structure to iterate forward and construct the change across time. One more detail, to facilitate interpretation, it will be useful to compute the Euler equation associated with asset holdings when the borrowing constraint does not bind. This euler equation is:

$$-u'(c_{ii}(a, z)) = \beta \mathbb{E} \left\{ -\sigma_\epsilon \frac{\partial \pi_{ii}(a', z') / \pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right\}, \quad (73)$$

which says that the agent should be indifferent between the marginal utility of consumption forgone to hold some more assets and two components (i) the benefit from how a change in assets changes in their variety choice and (ii) the direct benefit of the returns on the assets evaluated at the marginal utility of consumption.

Redo. Digression on chain rule. I'm going to

$$v(a', z') = v(g(a, z, d), z') \quad (74)$$

where I substitute in the policy function for a' . Then first term inside indicates that v depends upon the choice of a' and this works through the policy function. And the dependence of v on d (and not through assets) is implicit. Then the total derivative of this is

$$\frac{dv(g(a, z, d), z')}{dd} = \frac{\partial v}{\partial a'} \frac{dg}{dd} + \frac{\partial v(\overline{g(a, z, d)}, z')}{\partial d} \quad (75)$$

So the first term is the partial change of v with respect to a' times how the policy function totally changes with respect to d . The second term is the partial change of v with respect to d , **holding fixed assets** at their chosen level. That's why I'm emphasizing the bar on top. Now what is confusing to me is that this has partial, not total derivatives. But this term is mathematically the same as

$$\frac{\partial v(\overline{g(a, z, d)}, z')}{\partial d} = \frac{dv(a', z')}{dd} \quad (76)$$

where the RHS is the total derivative of v treating a' as a parameter. In other words, the LHS says, how does v change (everything else) holding fixed assets. The RHS says how does ev-

everything else change holding fixed assets. There the same. And the RHS is the value function evaluated at the new states a', z' .

Totally differentiating the value function gives

$$\frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} + u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a - u'(c_{ii}(a, z)) \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} + \beta E \frac{dv_i(g_{ii}(a, z), z')}{dd_{ij}/d_{ij}} \quad (77)$$

Then the derivative of the continuation value function is:

$$\frac{dv_i(g(a, z), z')}{dd_{ij}/d_{ij}} = \underbrace{\left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right]}_{\frac{\partial v_i(g_{ii}(a, z), z')}{\partial a}} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} + \quad (78)$$

$$-\sigma_\epsilon \frac{d\pi_{ii}(a', z')/\pi_{ii}(a', z')}{dd_{ij}/d_{ij}} + u'(c_{ii}(a', z')) \frac{dR}{dd_{ij}/d_{ij}} a' - u'(c_{ii}(a', z')) \frac{dg_{ii}(a', z')}{dd_{ij}/d_{ij}} + \beta E \frac{dv_i(g_{ii}(a', z'), z'')}{dd_{ij}/d_{ij}} \quad (79)$$

And now combine and collect terms so

$$\frac{dv_i(a, z)}{dd_{ij}/d_{ij}} = -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} \quad (80)$$

$$+ \underbrace{u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a}_{\gamma_{ii}(a, z)} \quad (81)$$

$$+ \underbrace{\left\{ -u'(c_{ii}(a, z)) + \beta E \left[-\sigma_\epsilon \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right] \right\}}_{\delta_{ii}(a, z)} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}} \quad (82)$$

$$+ \beta E \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}} + u'(c_{ii}(a', z')) \frac{dR}{dd_{ij}/d_{ij}} a' \dots \right\} \quad (83)$$

Let me walk through the interpretation of each term:

- $-\sigma_\epsilon \frac{d\pi_{ii}(a,z)/\pi_{ii}(a,z)}{dd_{ij}/d_{ij}}$ is the standard gains from trade term reflecting the idea that gains work through changes in expenditures across different varieties. With static logit, this is exactly the ACR formula.
- $u'(c_{ii}(a,z)) \frac{\partial R}{\partial d_{ij}/d_{ij}} a$ or what I'm labeling as $\gamma_{ii}(a,z)$ is what I would call how trade facilitates more risk sharing. I think as trade costs decline the amount of resources available for risk sharing expands and this changes the interest rate. Which way does it go?
- The third term which I'm labeling as $\delta_{ii}(a,z)$ is the Euler equation for assets. Honestly, it's pretty cool the way this shows up here. The idea is that if the household is unconstrained, then this term is zero as there is no gain through changes in asset behavior. Asset holdings are already chosen optimally so that margins are equated, thus, on the margin any benefit of lower trade costs on changes in asset behavior is zero. Essentially an application of the Envelope Theorem.

Now in this economy, this term may not be zero because of borrowing constrained households, thus this term is positive and may (see below) represent a gain from trade. What this is picking up is that a change in trade costs are relaxing the constraints on some households and get's them back on their euler equation.

Finally, notice how the outside brackets is multiplied by the change in the asset policy function. Again, this is super cool. What this picks up is that if the household is still constrained, then assets can't change so the outside term is zero and, thus, overall the second term is zero. So the only people that benefit and contribute to social welfare through these effects are those on the margin between constrained and not-constrained.

- The final term is about this continuing on into the infinite future.

Iterating on (83) into the future, the gains from trade for a household with states a, z today are

$$\frac{\partial v_i(a,z)}{\partial d_{ij}/d_{ij}} = \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ -\sigma_\epsilon \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}} + \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\} \quad (84)$$

Where the first component is the expected discounted gains from substitution, gains from risk sharing and the relaxation of borrowing constraints. Combining (84) and (65) yields the following proposition for the gains from trade

Proposition 5 (The Welfare Gains from Trade) *The welfare gains from trade are given by*

$$\frac{dW_i}{dd_{ij}/d_{ij}} = \sum_{a,z} \left\{ \frac{dv_i(a,z)}{dd_{ij}/d_{ij}} + v_i(a,z) \frac{d\lambda_i(a,z)/\lambda_i(a,z)}{dd_{ij}/d_{ij}} \right\} \lambda_i(a,z).$$

which reflects the change in household level gains and how the distribution of households changes. Household level gains are given by

$$\frac{\partial v_i(a, z)}{\partial d_{ij}/d_{ij}} = \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ -\sigma_{\epsilon} \frac{d\pi_{ii}(a_t, z_t)/\pi_{ii}(a_t, z_t)}{dd_{ij}/d_{ij}} + \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\}$$

where each term represents:

- Gains from substitution: $-\sigma_{\epsilon} \frac{d\pi_{ii}(a, z)/\pi_{ii}(a, z)}{dd_{ij}/d_{ij}}$.
- Gains from risk sharing: $\gamma_{ij}(a, z) = u'(c_{ii}(a, z)) \frac{dR}{dd_{ij}/d_{ij}} a$
- Gains from relaxing borrowing constraints:

$$\delta_{ii}(a, z) = \left\{ -u'(c_{ii}(a, z)) + \beta \mathbb{E} \left[-\sigma_{\epsilon} \frac{\partial \pi_{ii}(a', z')/\pi_{ii}(a', z')}{\partial a'} + u'(c_{ii}(a', z')) R \right] \right\} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}}$$

Proposition 5 nests several interesting cases that connect with the literature and further illustrate the mechanics.

2.1. Static, Log Preferences

The first is the non-assets, static, log preference case. This delivers the benchmark gains from trade formula in Arkolakis et al. (2012). The first step is to derive the trade elasticity. A couple observations are necessary.

- From the formula for the intensive margin elasticity (51) and because there is no asset choice then $\theta_{ij}(z)^I$ is zero, so any change in prices are fully offset by a change in consumption.
- Second, because there is no asset choice and household level shocks are exogenously specified, then the distribution elasticity is zero.
- Third, the choice probabilities become independent of household level productivity, so

$$\pi_{ij}(z) = \exp \left(\frac{\log \left(\frac{w_i z}{p_{ij}} \right)}{\sigma_{\epsilon}} \right) / \sum_{j'} \exp \left(\frac{\log \left(\frac{w_i z}{p_{ij'}} \right)}{\sigma_{\epsilon}} \right)$$

$$\pi_{ij} = \exp \left(\frac{-\log(p_{ij})}{\sigma_{\epsilon}} \right) / \sum_{j'} \exp \left(\frac{-\log(p_{ij'})}{\sigma_{\epsilon}} \right).$$

And thus, the $\Phi_i(z)$ showing up in the extensive margin calculation (53) is independent of z .

- Then the final observation is that the partial derivative of the i, j choice value function $\frac{\partial v_{ij}(z)}{\partial d_{ij}/d_{ij}} = -1$ and zero everywhere else.

Then following Proposition 4 and (49) the trade elasticity is

$$\theta_{ij} = \sum_z \left\{ 0 + -\frac{1}{\sigma_\epsilon} - \frac{\partial \Phi_i / \Phi_i}{\partial d_{ij} / d_{ij}} + 0 \right\} \omega_{ij}(z) - \sum_z \left\{ 0 - \frac{\partial \Phi_i / \Phi_i}{\partial d_{ij} / d_{ij}} + 0 \right\} \omega_{ii}(z)$$

$$\theta = -\frac{1}{\sigma_\epsilon}$$

where the second line follows because the terms inside the brackets are independent of z and thus can be pulled outside and the weights $\omega_{ij}(z)$ sum to one. What this means is the trade elasticity is constant and parameterized by the dispersion in tastes. I think the feature delivering this is that the elasticities at the micro-level are constant, so then the aggregate elasticity simply follows because I don't need to say anything about what is going on with the weights.

Now combining these observations and mechanically following Proposition 5 the gains from trade are

$$\frac{dW_i}{dd_{ij}/d_{ij}} = -\frac{1}{\theta} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}} \quad (85)$$

. which is exactly the Arkolakis et al. (2012) formula. The change in welfare gains from equal the inverse of trade elasticity multiplied by how much the home trade share changes.

Corollary 1 (ACR 2012) *In the static heterogenous agent trade model the trade elasticity is*

$$\theta = -\frac{1}{\sigma_\epsilon}$$

and the gains from trade are given by

$$\frac{dW_i}{dd_{ij}/d_{ij}} = -\frac{1}{\theta} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}. \quad (86)$$

2.2. Dynamic, Log Preferences

This example is interesting because it retains an aggregate constant trade elasticity, but at the micro-level it is not quite with things canceling in a way during aggregation. Second, the welfare gains from trade formula looks like ACR kind of thing. Because this is a bit more involved I'm going to be super systematic about this.

Step 1: Individual Choices. With log preferences the j choice value function is

$$v_{ij}(a, z) = \max_{a' \in \mathcal{A}} \left\{ \log \left(\frac{Ra + wz - a'}{p_{ij}} \right) + \beta \mathbb{E}[v_i(a', z')] \right\} \quad (87)$$

which is then

$$v_{ij}(a, z) = \max_{a' \in \mathcal{A}} \left\{ \log(Ra + wz - a') + \beta \mathbb{E}[v_i(a', z')] \right\} - \log p_{ij} \quad (88)$$

which then leads to the observation that the optimal a' conditional on a choice j is **independent** of the price and the choice j . So what is going on is if you consume an expensive or cheap good, then consumption simply scales up or down so that assets next period are exactly the same. This observation has the implication that expenditures on consumption are the same across choices. Compare households expenditures with the same state a, z but different choices. Equation (88) implies

$$p_{ij}c_{ij}(a, z) = p_{ii}c_{ii}(a, z) \quad (89)$$

so within states, people always spend the same amount. This fact will be useful below.

Finally, this observation implies that the choice probabilities are independent of the state only prices matter so

$$\pi_{ij}(a, z) = \exp \left(\frac{v_{ij}(a, z)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{v_{ij'}(a, z)}{\sigma_\epsilon} \right) \quad (90)$$

$$\pi_{ij} = \exp \left(\frac{-\log p_{ij}}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{-\log p_{ij'}}{\sigma_\epsilon} \right) \quad (91)$$

which is exactly the same as discussed above in the static model. These observations are all consistent with the Generalized Euler Equation below. To see this

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \max \left\{ \beta R_i \mathbb{E} \left[\sum_{j'} \pi_{ij'}(a', z') \frac{u'(c_{ij'}(a', z'))}{p_{ij'}} \right], u' \left(\frac{Ra + w_i - \phi_i}{p_{ij}} \right) \right\} \quad (92)$$

and then impose log preferences and notice that

$$(Ra + wz - a')^{-1} = \max \left\{ \beta R \mathbb{E} \left[\sum_{j'} \pi_{ij'}(a', z') (Ra' + wz - a'')^{-1} \right], (Ra + w - \phi_i)^{-1} \right\} \quad (93)$$

and then because the term multiplying the $\pi_{ij'}$'s does not depend upon j it can be pulled out

and

$$(Ra + wz - a')^{-1} = \max \left\{ \beta R \mathbb{E}(Ra' + wz' - a'')^{-1}, (Ra + w - \phi_i)^{-1} \right\} \quad (94)$$

and thus the asset choice is independent from the variety choice j .

Step 2: Micro Trade Elasticities. I'm going to be super systematic about this:

- Starting with (51) and because the asset choice is independent of prices, the intensive margin elasticity $\theta_{ij}(a, z)^I$ is zero. This is not obvious actually because of how prices would enter into v_i . I do think one can expand out and completely separate out the effects of prices.
- The distribution elasticity is zero from (63) because assets are not responding to changes in prices and what about π s (but these are independent of a and z so there is no differential change? This is not clear from formula. Need to articulate this better.
- The extensive margin elasticity is:

$$\theta_{ij}(a, z)^E = \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a, z)}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (95)$$

$$= -\frac{1}{\sigma_\epsilon} \frac{\partial p_{ij}/p_{ij}}{\partial d_{ij}/d_{ij}} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i(z)/\Phi_i(z)}{\partial d_{ij}/d_{ij}} \quad (96)$$

$$= -\frac{1}{\sigma_\epsilon} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (97)$$

where the first line removes the a, z indexing of Φ_i because they don't shape the choice probabilities. The next line then partially differentiates the value function with respect to the change in trade costs and I'm exploiting how with log preferences one can pull out the price term. And then the final line notes that the price elasticity is minus one. One more fact that:

$$\theta_{ii}(a, z)^E = \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} \quad (98)$$

where a key thing to notice is that the i, i elasticity is the same as the second and third terms above in (97).

It's worth emphasizing that the micro trade elasticities are **not** constant across states a, z . Unlike the static model with log preferences, they are varying by income and assets as the derivative

of the value function is showing up. But what **is** occurring is that across different destinations, within states, they are varying in the same exact way. This is one aspect of this case that facilitates aggregation. However, the necessary aspect is that the expenditure weights work out in the right way, I show this next.

Step 3: Expenditure Weights. Recall that the micro level trade elasticities when aggregated are weighted by

$$\omega_{ij}(a, z) = \frac{p_{ij}c_{ij}(a, z)\pi_{ij}(a, z)\lambda_i(a, z)}{M_{ij}}. \quad (99)$$

and note that we can relabel $p_{ij}c_{ij}(a, z) = x(a, z)$ given (89), that expenditures are independent of the destination. With the choice probabilities independent of a, z the weights become

$$\omega_{ij}(a, z) = \frac{x(a, z)\pi_{ij}\lambda_i(a, z)}{\sum_{a,z} x(a, z)\pi_{ij}\lambda_i(a, z)}, \quad (100)$$

$$= \frac{x(a, z)\lambda_i(a, z)}{\sum_{a,z} x(a, z)\lambda_i(a, z)} \quad (101)$$

which are independent of source j . This is the second important observation that will facilitate aggregation.

Step 4: The Trade Elasticity. Now just mechanically follow Proposition 4:

$$\begin{aligned} \theta_{ij} &= \sum_{a,z} \left\{ 0 + -\frac{1}{\sigma_\epsilon} + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} + 0 \right\} \omega_i(a, z) \\ &\quad - \sum_z \left\{ 0 + \beta \mathbb{E} \frac{\partial v_i(a', z')}{\partial d_{ij}/d_{ij}} - \frac{\partial \Phi_i/\Phi_i}{\partial d_{ij}/d_{ij}} + 0 \right\} \omega_i(a, z) \\ &= -\frac{1}{\sigma_\epsilon} \end{aligned} \quad (102)$$

where the last line follows because the a, z terms in the micro level trade elasticities exactly cancel given that expenditure weights are source independent. And the aggregate trade elasticity is constant and parameterized by the dispersion in tastes.

Step 5: The Grains From Trade. Then from here I can just follow Proposition 5. First the

individual gains are

$$\frac{\partial v_i(a, z)}{\partial d_{ij}/d_{ij}} = \underbrace{-\frac{1}{\theta(1-\beta)} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}}_{ACR} + \mathbb{E} \sum_{t=0}^{\infty} \beta^t \left\{ \gamma_{ii}(a_t, z_t) + \delta_{ii}(a_t, z_t) \right\}$$

where the first term is exactly in the static model except for the discounting bit. But what facilitates this is that the choice probabilities are independent of a, z and it can be pulled out of the expected discounted sum stuff. Then the subsequent terms take a slightly cleaner form:

- Gains from risk sharing: $\gamma_{ij}(a, z) = \frac{dR}{dd_{ij}/d_{ij}} \frac{a}{c_{ii}(a, z)}$
- Gains from relaxing borrowing constraints:

$$\delta_{ii}(a, z) = \left\{ -c_{ii}(a, z)^{-1} + \beta \mathbb{E}[c_{ii}(a', z')^{-1} R] \right\} \frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}}$$

One final step. Claim is that because the asset policy function g is independent of the price of varieties, then any change in trade costs will not affect R and thus the total derivative $\frac{dR}{dd_{ij}/d_{ij}}$ equals zero and then the total derivative $\frac{dg_{ii}(a, z)}{dd_{ij}/d_{ij}}$ on the asset policy function is zero. And then $\frac{d\lambda_i(a, z)/\lambda_i(a, z)}{dd_{ij}/d_{ij}}$ is zero as well.

So there is a super strong result:

Corollary 2 (Separation of Trade and Heterogeneity) *In the dynamic heterogenous agent trade model the trade elasticity is*

$$\theta = -\frac{1}{\sigma_\epsilon}$$

and the gains from trade are given by

$$\frac{dW_i}{dd_{ij}/d_{ij}} = -\frac{1}{\theta(1-\beta)} \times \frac{d\pi_{ii}/\pi_{ii}}{dd_{ij}/d_{ij}}. \quad (103)$$

Should check this stuff on computer.

C. Appendix: Endogenous Grid Method

First, I'm going to derive the Euler equation for this model. I'll abstract from the situation in which the HH is at the borrowing constraint.

Focus on the within a variety choice component, the households value function can be written as:

$$v_{ij}(a, z) = \max_{a'} u \left(\frac{R_i a + w_i z - a'}{p_{ij}} \right) + \beta E v(a', z') \quad (104)$$

then the first order condition associated with this problem is:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \beta E \frac{\partial v(a', z')}{\partial a'} \quad (105)$$

which is saying that, conditional on a variety choice the left hand side is the loss in consumption units which is $1/p_{ij}$ evaluated at the marginal utility of consumption and then this is set equal to the marginal gain from saving a bit more which is how the value function changes with respect to asset holdings. Now we can arrive at the $\frac{\partial v(a', z')}{\partial a'}$ in the following way, so start from the log-sum expression for the expected value function

$$\mathbb{E}_\epsilon v(a', z') = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right) \right\} \quad (106)$$

and then differentiate this with respect to asset holdings which gives:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \left(\frac{\sigma_\epsilon}{\sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right)} \right) \left[\sum_{j'} \exp \left(\frac{v_{ij}(a', z')}{\sigma_\epsilon} \right) \frac{1}{\sigma_\epsilon} \frac{\partial v_{ij}(a', z')}{\partial a'} \right] \quad (107)$$

Then if you look at this carefully and notices how the choice probabilities from (10) are embedded in here, we have:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \sum_{j'} \pi_{ij}(a', z) \frac{\partial v_{ij}(a', z')}{\partial a'} \quad (108)$$

and then we can just apply the Envelop theorem to the value functions associated with the discrete choices across the options:

$$\frac{\partial \mathbb{E}_\epsilon v(a', z')}{\partial a'} = \sum_{j'} \pi_{ij}(a', z) \frac{u'(c_{ij}(a', z')) R_i}{p_{ij}} \quad (109)$$

So then putting everything together we have:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right] \quad (110)$$

where this has a very natural form: you set the marginal utility of consumption today equal to the marginal utility of consumption tomorrow adjusted by the return on delaying consumption, and the expected value of the marginal utility of consumption which reflects how the uncertainty over both ones' preference over different varieties and shocks to efficiency units. Taking into account the borrowing constraint then gives the generalized Euler equation from which the endogenous grid method will exploit:

$$\frac{u'(c_{ij}(a, z))}{p_{ij}} = \max \left\{ \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right], u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \right\} \quad (111)$$

3.1. EGM-Discrete Choice Algorithm

Here is a proposed approach. This focuses on just the consumer side in one country i .

0. Set up an asset grid as usual. Then guess (i) a consumption function $g_{c,ij}(a, z)$ for each a , z , and product choice j and (ii) choice specific value function $v_{ij}(a, z)$.
1. Compute the choice probabilities from (10) for each (a, z) combination, given the guessed value functions.
1. Given the consumption function and choice probabilities compute the RHS of (12) first.
2. Then invert to find the new updated consumption choice so

$$c_{ij}(\tilde{a}, z) = u'^{-1} \left\{ p_{ij} \max \left\{ \beta R_i E_{z'} \left[\sum_{j'} \pi_{ij}(a', z') \frac{u'(c_{ij}(a', z'))}{p_{ij}} \right], u' \left(\frac{R_i a + w_i - \phi_i}{p_{ij}} \right) \right\} \right\} \quad (112)$$

where u'^{-1} is the inverse function of the marginal utility of consumption.

Side note: One of the interesting things about this equation is that the direct j component on the RHS that only affects the consumption choice is through the price. Can this be exploited? We also know the choice probabilities need to sum to one, so is there a way to map the consumption choice into the choice probabilities? Also, can interpolation be done once how p scales things...

3. The key issue in this method is that we have found $c_{ij}(\tilde{a}, z)$ where the consumption function is associated with some asset level that is not necessarily on the grid. The solution is to (i) use the budget constraint and infer \tilde{a} given that a' was chosen above (that's where we started), z , and $c_{ij}(\tilde{a}, z)$. Now we have a map from \tilde{a} to a' for which one can use interpolation to infer the a' chosen given a where a is on the grid.
- Do steps 2. and 3. for each j variety choice. This then makes the function $g_{a,ij}(a, z)$ mapping each state and j choice (today) into a', z' states and then from the budget constraint we have an associated consumption function $g_{c,ij}(a, z)$
4. Compute the $E[v(g_{a,ij}(a, z), z')]$. This is performed in the `make_Tv_upwind!` function. It fixes a country j , then works through shocks and asset states today and from the policy function $g_{a,ij}(a, z)$ figures out the asset choice tomorrow. Then the $E[v(g_{a,ij}(a, z), z')]$ is (11) over the different variety choices tomorrow (this is the integration over ϵ) multiplied by the probability of z' occurring (this is the integration over z).
5. Given 4. update the value function using the bellman equation evaluated at the optimal policies:

$$Tv_{ij}(a, z) = u(g_{c,ij}(a, z)) + \beta E[v(g_{a,ij}(a, z), z')] \quad (113)$$

6. Compare old and new policy functions, old and new value functions, and then update accordingly.

D. Appendix: The Planning Problem

As above, I focus on a utilitarian social welfare function so Pareto weights across households, within a country, are the same and then across countries they are weighted proportional to the number of households residing in those countries:

$$W = \sum_{t=0}^{\infty} \sum_i \sum_z \beta^t v_i(z, t) L_i \lambda_i(z, t), \quad (114)$$

and here v_i a households utility in country i with the preference shocks integrated out. Now, I'm going to place the social welfare function in sequence space and then unpack the benefits from the preference shock in the following way:

$$W = \sum_{t=0}^{\infty} \sum_i \sum_j \sum_z \beta^t \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t) \quad (115)$$

so the inner term is period utility given the associated consumption allocation c_{ij} and then the expected value of the preference shock conditional on the choice probability $\pi_{ij}(z, t)$. This inner term is then weighted by the number of households that receive that utility, i.e. the choice probability times the mass of households with shock z at date t . The sum across j adds up all households in country i . Then the sum across i reflects that this is global welfare.

One more point about the inner term in (115), my claim is that with the Type 1 extreme value shocks:

$$E[\epsilon \mid \pi_{ij}(z, t)] = -\sigma_\epsilon \log \pi_{ij}(z, t) \quad (116)$$

where this is like the standard “selection correction” where if π becomes smaller, then this value becomes larger meaning only those with the largest relative shocks are chosen and higher utility for those, conditional on being selected, is felt.

Given this formulation, the planner then does the following: he is choosing consumption and choice probabilities for all country pair combinations, state by state, for the infinite future. The Lagrangian associated with the Planning Problem is:

$$\begin{aligned} \mathcal{L} = & \sum_{t=0}^{\infty} \sum_i \sum_j \sum_z \beta^t \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} \pi_{ij}(z, t) L_i \lambda_i(z, t), \\ & + \sum_{t=0}^{\infty} \sum_i \beta^t \chi_i(t) \left\{ Y_{it} - \sum_j \sum_z d_{ji} c_{ji}(z, t) \pi_{ji}(z, t) L_j \lambda_j(z, t) \right\} \\ & + \sum_{t=0}^{\infty} \sum_i \sum_z \beta^t \chi_{2i}(z, t) \left\{ 1 - \sum_j \pi_{ij}(z, t) \right\} L_i \lambda_i(z, t) \end{aligned} \quad (117)$$

where the first term is the objective function, the second line is the resource constraint which says that output from country i must equal the consumption of commodity i globally including the transport costs. Then the third line is there to ensure that choice probabilities are probabilities and sum to one. The final thing I’m doing is that I’m scaling the multipliers by β^t so that the algebra is a bit easier.

Then associated with this problem are two first order conditions. The first one is consumption

in i with respect to variety j so:

$$\frac{\partial \mathcal{L}}{\partial c_{ij}(z, t)} = \beta^t u'(c_{ij}(z, t)) \pi_{ij}(z, t) L_i \lambda_i(z, t) - \beta^t \chi_j(t) d_{ij} \pi_{ij}(z, t) L_i \lambda_i(z, t) = 0 \quad (118)$$

$$\Rightarrow u'(c_{ij}(z, t)) = \chi_j(t) d_{ij}, \quad (119)$$

which says that the marginal utility of consumption of (i consuming variety j) should equal it's costs. What is this cost, it's the j 's multiplier adjusted by the trade cost d_{ij} which gives this "price" like interpretation of the multiplier, it's like the shadow value of commodity j which reflects how scarce or not the commodity is then multiplied by the transport costs.

This first order condition has several implications. First, because the right hand size is independent of z , then $u'(c_{ij}(z, t)) = u'(c_{ij}(z', t)) = u'(\bar{c}_{ij}(t))$ for all z, z' combinations. So within choice, the marginal utility of consumption is equated.

Second, across variety choice, the ratio of marginal utility across variety j is:

$$\frac{u'(\bar{c}_{ij}(t))}{u'(\bar{c}_{ij'}(t))} = \frac{\chi_j(t) d_{ij}}{\chi_{j'}(t) d_{ij'}} \quad (120)$$

which says that consumption differences relate to the ratio of the multipliers on the resource constraint and the trade costs. This again gives the price like interpretation of the multipliers, i.e. that differences in the ratio of the marginal utility of consumption reflect relative scarcity or the shadow values.

The second first order condition is with respect to the choice probabilities. So

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \pi_{ij}(z, t)} &= \beta^t \left\{ u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] \right\} L_i \lambda_i(z, t) + \beta^t \frac{\partial E[\epsilon \mid \pi_{ij}(z, t)]}{\partial \pi_{ij}} \pi_{ij}(z, t) L_i \lambda_i(z, t) \\ &\quad - \beta^t \chi_j(t) d_{ij} c_{ij}(z, t) L_i \lambda_i(z, t) - \beta^t \chi_{2i}(z, t) \pi_{ij}(z, t) L_i \lambda_i(z, t) = 0 \end{aligned} \quad (121)$$

where the first two terms are the marginal, social benefit of changing the choice probabilities. This reflects how utility shifts by adding more households to that choice and then how the expected preference shock changes. The last two terms reflect the costs of changing the choice probabilities which are the resources to provide the additional consumption and the cost of moving households out of other choices which is what the multiplier $\chi_{2i}(z, t)$ represents.

Further simplifying gives:

$$\frac{\partial \mathcal{L}}{\partial c_{ij}(z, t)} = u(c_{ij}(z, t)) + E[\epsilon \mid \pi_{ij}(z, t)] + \frac{\partial E[\epsilon \mid \pi_{ij}(z, t)]}{\partial \pi_{ij}} - \chi_j(t) d_{ij} c_{ij}(z, t) - \chi_{2i}(z, t) = 0. \quad (122)$$

Then inserting the observations made above about the Type 1 extreme value distribution and then connecting things with the consumption allocation one has

$$u(c_{ij}(t)) - \sigma_\epsilon \log \pi_{ij}(z, t) - \sigma_\epsilon - u'(c_{ij}(t)) c_{ij}(t) = \chi_{2i}(z, t). \quad (123)$$

Then some algebra gets toward a closed-form expression for the choice probability

$$-\sigma_\epsilon \log \pi_{ij}(z, t) = -u(c_{ij}(t)) + u'(c_{ij}(t)) c_{ij}(t) + \sigma_\epsilon + \chi_{2i}(z, t), \quad (124)$$

$$\pi_{ij}(z, t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} + 1 \right) / \exp(\chi_{2i}(z, t) / \sigma_\epsilon). \quad (125)$$

The choice probabilities must sum to one, so we can set the multiplier so

$$\exp(\chi_{2i}(z, t) / \sigma_\epsilon) = \sum_{j'} \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} + 1 \right), \quad (126)$$

which implies

$$\chi_{2i}(z, t) = \sigma_\epsilon \log \left\{ \sum_{j'} \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} + 1 \right) \right\}, \quad (127)$$

Notice how this multiplier is looking like the expected utility term when prior to the realization to the preference shock. Then the choice probability is

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t)) c_{ij'}(t)}{\sigma_\epsilon} \right), \quad (128)$$

which is independent of z . This has the standard Type 1 shape, but the inner most term says that the choice probability should reflect the “net” social benefit of having someone chose that good. The net part is the utility a household receives net of the cost of providing that amount of the consumption. And the cost is, well, c converted into utils which is what the marginal utility bit is doing.

The final thing I'm going to do is compute the social gain to a small change in trade costs, so

$$\partial W = - \sum_{t=0}^{\infty} \beta^t \chi_j(t) c_{ij}(t) \pi_{ij}(t) L_i \partial d_{ij} \quad (129)$$

$$= - \sum_{t=0}^{\infty} \beta^t u'(c_{ij}(t)) c_{ij}(t) \pi_{ij}(t) L_i \partial d_{ij} / d_{ij} \quad (130)$$

where the last line inserts the relationship between the multiplier and the marginal utility of consumption. Now this thing says that the change in welfare equals essentially how much the resource constraint is relaxed by the change in trade costs. So it's like the $c_{ij}(t) \pi_{ij}(t) L_i$ is how much stuff people in i get from g and $\partial d_{ij} / d_{ij}$ this is perturbing it by the percent change in trade costs, then this bit $u'(c_{ij}(t))$ converts it into utils.

Proposition 6 (The Efficient Allocation and the Gains from Trade) *The allocation that satisfies the Centralized Planning Problem is characterized by consumption allocations satisfying:*

$$u'(c_{ij}(t)) = \chi_j(t) d_{ij}$$

where $\chi_j(t)$ is the shadow price of variety j . The choice probabilities are

$$\pi_{ij}(t) = \exp \left(\frac{u(c_{ij}(t)) - u'(c_{ij}(t)) c_{ij}(t)}{\sigma_\epsilon} \right) / \sum_{j'} \exp \left(\frac{u(c_{ij'}(t)) - u'(c_{ij'}(t)) c_{ij'}(t)}{\sigma_\epsilon} \right)$$

and the gains from trade are given by

$$\frac{\partial W}{\partial d_{ij} / d_{ij}} = \frac{1}{1 - \beta} \times u'(c_{ij}(t)) c_{ij}(t) \pi_{ij}(t) L_i.$$

The one issue with this last result is that it's a bit opaque relative to the other welfare results that I derived. Let me connect them. So per the arguments above, I can write the ex-ante utility and inserting the allocations associated with the planner as

$$v_i(t) = -\sigma_\epsilon \log \pi_{ii} + u(c_{ii}(t)) \quad (131)$$

and then

$$\frac{\partial v_i(t)}{\partial d_{ij} / d_{ij}} = -\sigma_\epsilon \frac{\partial \pi_{ii} / \pi_{ii}}{\partial d_{ij} / d_{ij}} \quad (132)$$

so the gains only work through the home share. Notice this holds if this is a global change or

not. Now this elasticity is

$$\frac{\partial \pi_{ii}/\pi_{ii}}{\partial d_{ij}/d_{ij}} = -\frac{\pi_{ij}}{\sigma_\epsilon} \left\{ u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} - \left[u'(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} + u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} c_{ij}(t) \right] \right\} \quad (133)$$

$$= -\frac{\pi_{ij}}{\sigma_\epsilon} u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} c_{ij}(t) \quad (134)$$

Then notice the following from the consumption allocation that

$$u'(c_{ij}(t)) = \chi_j(t) d_{ij} \Rightarrow u''(c_{ij}(t)) \frac{\partial c_{ij}(t)}{\partial d_{ij}/d_{ij}} = \chi_j(t) d_{ij} \quad (135)$$

where I'm just differentiating both sides by d_{ij} and then dividing through by d to make an elasticity. Then this implies that

$$\frac{\partial \pi_{ii}(t)/\pi_{ii}(t)}{\partial d_{ij}/d_{ij}} = \frac{\pi_{ij}(t)}{\sigma_\epsilon} u'(c_{ij}(t)) c_{ij}(t) \quad (136)$$

and then

$$\frac{\partial v_i(t)}{\partial d_{ij}/d_{ij}} = \pi_{ij} u'(c_{ij}(t)) c_{ij}(t) \quad (137)$$

which means that the total change in social welfare equals

$$\frac{\partial W}{\partial d_{ij}/d_{ij}} = \frac{\partial W_i}{\partial d_{ij}/d_{ij}} = \frac{1}{1-\beta} \times u'(c_{ij}(t)) c_{ij}(t) \pi_{ij}(t) L_i \quad (138)$$

and I'm done.
